Abstract

Carbonates are abundant sedimentary minerals at the surface and sub-surface of the Earth and they have been proposed as tracers of liquid water in extraterrestrial environments. Their formation mechanism is since generally associated with aqueous alteration processes. Recently, carbonate minerals have been discovered on Mars' surface by different orbital or rover missions. In particular, the phoenix mission has measured from 1 to 5% of calcium carbonate (calcite type) within the soil (Smith P.H. et al., 2009). These occurrences have been reported in area were the relative humidity is significantly high (Boynton et al., 2009). The small concentration of carbonates suggests an alternative process on mineral grain surfaces (as suggested by Shaheen et al., 2010) than carbonation in aqueous conditions. Such an observation could rather point toward a possible formation mechanism by dust-gas reaction under current Martian conditions. To understand the mechanism of carbonate formation under conditions relevant to current Martian atmosphere and surface, we designed an experimental setup consisting of an infrared microscope coupled to a cryogenic reaction cell (IR-CryoCell setup). Three different mineral precursors of carbonates (Ca and Mg hydroxides, and a hydrated Ca silicate formed from Ca$_2$SiO$_4$), low temperature (from -10 to +30°C), and reduced CO$_2$ pressure (from 100 to 2000 mbar) were utilized to investigate the mechanism of gas-solid carbonation at mineral surfaces. These mineral materials are crucial precursors to form Ca and Mg carbonates in humid environments (0 < relative humidity < 100%) at dust-CO$_2$ or dust-water ice-CO$_2$ interfaces. Our results reveal a significant and fast carbonation process for Ca hydroxide and hydrated Ca silicate. Conversely, only a moderate carbonation is observed for the Mg hydroxide. These results suggest that gas-solid carbonation process or carbonate formation at the dust-water ice-CO$_2$ interfaces could be a...
currently active Mars' surface process. To the best of our knowledge, we report for the first time that calcium carbonate can be formed at a negative temperature (-10°C) via gas-solid carbonation of Ca hydroxide. We note that the carbonation process at low temperature (<0°C) described in the present study could also have important implications on the dust-water ice-CO2 interactions in cold terrestrial environments (e.g. Antarctic).

Keywords: Carbonates; Gas-solid carbonation; Mars; Low temperature; Infrared Microscopy; Ca and Mg Hydroxides.
1. Introduction

The biotic and abiotic (i.e. chemical) formation of carbonates plays a crucial role in the global carbon cycle on Earth. In addition, carbonate minerals often sequester various trace elements (actinides and lanthanides), metalloids, and heavy metals, and thus control in part their global cycling (e.g. Paquette and Reeder, 1995; Stumm and Morgan, 1995; Sigg et al., 2000). In general, carbonate minerals can be formed in natural or artificial environments by three different mechanisms (e.g. Montes-Hernandez et al., 2010a): (1) aqueous nucleation-growth in homogeneous or heterogeneous systems (aqueous conditions), for example, the chemical or biogenic formation of carbonates in lakes, oceans, CO$_2$ storage sites, natural caves; (2) gas-solid carbonation of alkaline minerals (fine particles) in the presence of adsorbed water (water humidity conditions, 0 < water activity < 1), for example carbonate formation in water-unsaturated soils, in terrestrial or extraterrestrial aerosols (Shaheen et al., 2010). This water has an important role in the surface chemistry of minerals as was shown by Galhotra et al., (2009) and Baltrusaitis and Grassian (2005) with zeolites and iron oxide surfaces; (3) dry gas-solid carbonation of granular/porous materials (dry conditions, water activity ≈ 0), for example, the industrial mineralization, recovery or capture of CO$_2$ at high temperatures in presence of alkaline binary oxides (CaO, MgO) or metastable, nanoparticle alkaline silicates (Montes-Hernandez et al., 2012).

In the Planetary Sciences context, carbonates are generally considered as indicators of aqueous alteration processes (Bandfield et al., 2003; Milliken and Rivkin, 2009; Boynton et al., 2009; Ehlmann et al., 2008; Michalski and Niles, 2010). In the case of Mars, huge deposits of surface carbonates remained undetected for a long period, and their suspected absence was used
to constrain the chemistry of a putative Martian ocean (Fairén et al., 2004). Evidences are now
growing for the presence of carbonates at the surface of the red planet, which include
observations of carbonate-rich outcrops (Ehlmann et al., 2008; Michalski and Niles, 2010) as
well as carbonates within the Martian dust (Bandfield et al., 2003; Boynton et al., 2009). The
aqueous alteration of mafic rocks in the presence of CO$_2$ is certainly an efficient mechanism for
carbonate synthesis, an alternative pathway of carbonate synthesis exists, which does not require
the presence of liquid water. This pathway involves reaction of a mineral substrate with CO$_2$ in
the presence of chemisorbed water (few angstroms to few nm thick layers), and was recently
tested and observed for terrestrial aerosols (Shaheen et al., 2010).

Here, we report on an experimental study of the kinetic of carbonation in liquid-water free
environment. We designed novel, state of the art experimental setup (IR-CryoCell) to investigate
the in-situ gas-solid carbonation (i.e. resolved in time), for temperature and pressure conditions
relevant to Mars. We studied carbonate synthesis starting from Ca and Mg hydroxides and an
amorphous silicate (synthesized from Ca$_2$SiO$_4$), at low temperature (from -10 to +30°C) and at
low CO$_2$ pressure (from 100 to 2000 mbar). These starting materials are known precursors to
form respective Ca and Mg carbonates in humid environments at dust-CO$_2$ or dust-water ice-CO$_2$
interfaces, at least under « terrestrial » conditions. They also can be expected to occur at the
surface of Mars and some asteroids (Mg hydroxide has been described on Ceres). We report here
laboratory experiments on gas-solid carbonation process at low temperature (<0°C), which
provides new insights on conditions for carbonate formation. We will show that gas-solid
carbonation can occur below the water frost point (at terrestrial atmospheric pressure), with
significant implications on the dust/water-ice/CO$_2$ interactions in cold environments.
2. Materials and methods

The experiments were performed using three different materials, Ca, Mg hydroxide and a Ca silicate hydrate. CO$_2$ is known to react with surface of CaO and MgO by adsorption (Ochs et al., 1998a; Ochs et al., 1998b) and produce carbonates as well the importance of OH groups to water adsorption on surfaces (Yamamoto et al., 2008). These substrates were chosen to mimic natural conditions and to catalyze reaction as their surfaces are terminated by OH groups: i) in order to form Ca-Mg carbonate by reaction with CO$_2$, a Ca and Mg source is needed; ii) the presence of hydroxyl groups in the starting material was requested to permit auto-catalysis of the reaction (Montes-Hernandez et al., 2010a); iii) the material had to be geologically relevant.

Brucite has not been detected on the Martian surface. However, various types of phyllosilicates have been now described over the planet, that are interpreted as aqueous alteration products of mafic rocks (see the recent review by Ehlmann et al., 2011). Such aqueous alteration processes can be accompanied by the production of brucite (Evans, 2008). Identification of brucite by its spectral properties is difficult since no diagnostic band is present in the NIR, with the exception of the 2.7 micrometer feature ubiquitous to almost all -OH bearing phases. Brucite has been diagnosed on some asteroids from observations in the mid-IR (together with carbonate). It is the case of the largest main-belt object, Ceres. In addition, MgO has been proposed as a condensation product in some solar nebula models, which should readily transform to brucite in the presence of gaseous water or humidity (Gail and Sedlmayr, 1999).

Portlandite has not been reported on Mars either. On Earth, it is almost always found in association with calcium carbonates, and is very difficult to observe due to its high reactivity with CO$_2$. We chose to study portlandite because of its high catalytic reactivity which enabled to
provide kinetic measurements under some hours. In addition, it is a structural analog to brucite and a number of X-(OH)$_2$ type hydroxide compounds (where X=Ni, Co, Fe, Mn, Cd). CaO has also been proposed as an intermediate compound by Shaheen et al. (2010) to explain the formation of calcium carbonate on Mars, which could readily transform to portlandite in the presence of gaseous H$_2$O or humidity.

Finally, we used an amorphous calcium silicate hydrate synthesized from larnite (Ca$_2$SiO$_4$). This material was chosen to represent an amorphous volcanic material. Volcanic activity has been widespread on Mars, and volcanoclastic deposits have been described (Ehlmann et al., 2011). We decided to use a pure calcium amorphous silicate (rather than a basaltic glass), in order to simplify the chemistry of the system. However, one might expect a more complex chemistry for Martian volcanic glasses. Our approach might appear too simplistic, but might provide grounds for understanding more complex chemistries.

2.1. Materials

**Portlandite:** Calcium hydroxide Ca(OH)$_2$ was provided by Sigma-Aldrich with 96% chemical purity (about 3% of CaCO$_3$) and 1% of other impurities. This material is characterized by platy nanoparticles (sheet forms) forming micrometric aggregates with high porosity and/or high specific surface area (15 m$^2$/g). Its infrared spectrum has revealed a small amount of adsorbed water at atmospheric conditions, around 0.01 gH$_2$O/gCa(OH)$_2$ determined by TGA. The portlandite sample was used without any physicochemical treatment.

**Brucite:** Magnesium hydroxide Mg(OH)$_2$ was provided by Fisher Scientific (UK). This material
is characterized by platy hexagonal microparticles. A small amount of adsorbed water at atmospheric conditions was detected by infrared spectroscopy. The brucite sample was crushed in a mortar before use.

**Amorphous calcium silicate hydrate:** This material was synthesized from synthetic larnite mineral (Ca₂SiO₄) by using a simple acidic treatment (2M HCl solution) at room lab temperature during 15 minutes. Then, consecutive dilutions with demineralized water were carried out until pH equal to 3. Finally, the solid was separated from the solution by centrifugation (10 minutes at 12000 rpm) and dried directly in the centrifugation flasks at 80°C for 48h. The larnite synthetic mineral was provided by A. Santos and it was synthesized as reported in Santos et al. (2009).

**Carbon dioxide:** Carbon dioxide CO₂ was provided by Linde Gas S.A. with 99.995% of chemical purity. This gas was directly injected in the cryogenic reaction cell without any treatment or purification.

### 2.2. Infrared microscope

An infrared microscope (BRUKER HYPERION 3000) coupled with a cryogenic cell (designed and built at IPAG) was used to obtain infrared spectra in transmission mode. The IR beam was focused through a 15x objective and the typical size of the spot on the sample was around 50x50 µm². The spectral resolution was 4cm⁻¹ and the spectra were recorded in transmission mode between 4000cm⁻¹ and 700cm⁻¹.

### 2.3. Cryogenic cell

An environmental cell was designed and built at IPAG in order to simulate low CO₂ pressure and
low temperature (LP-LT) close to Martian atmospheric conditions. A heating resistance coupled to a liquid N\textsubscript{2} circuit (77K) allows an efficient regulation of sample temperature from -180°C to +100°C. Additionally, a turbomolecular vacuum pump and a CO\textsubscript{2} cylinder were connected to reach a secondary vacuum and to inject a controlled CO\textsubscript{2} pressure into the reaction cell, respectively. Figure 1 shows a schematic diagram of all main parts of the IR-CryoCell setup.

2.4. Gas-solid carbonation experiments

For these measurements, the reacting Ca(OH)\textsubscript{2} particles, stored at atmospheric conditions, were manually deposited and compressed as a thin film on a KBr window. Then the KBr window was carefully placed in the reaction cell to be assembled to the microscope. All carbonation experiments have been carried out in presence of molecular water (adsorbed or crystallized as ice depending on the carbonation temperature) which catalyze the carbonation process. The carbonation temperatures used in this study were -10, 0, 10, 25 or 30°C and the CO\textsubscript{2} pressures were typically 100, 1000 and 2000 mbar. This pressure is higher than Martian pressure to accelerate the reaction due to a daily timescale limitation by the experimental setup. We note that the CO\textsubscript{2} gas has been directly injected into the reaction cell in presence or absence of atmospheric air. For the latter case, we started by fixing the water adsorbed onto the solid by cooling the cell at -60°C before making a high vacuum pumping for 10 min in order to remove exclusively the air from the reaction cell. After injection of CO\textsubscript{2} 10 to 15 infrared spectra have been collected as a function of time until an apparent spectroscopic equilibrium state is reached (3-6h).

Complementary carbonation experiments have been carried out by using Mg hydroxide (brucite: Mg(OH)\textsubscript{2}) and the amorphous calcium silicate hydrate as solid reactants, but, for these cases the carbonation temperature has been fixed at 25°C and 1 bar of CO\textsubscript{2} has been injected into the
reaction cell without air removal (more reacting system).

Each carbonation experiment has been repeated 2 times in order to verify its reproducibility. All carbonation experiments and their physicochemical conditions are summarized in Table 1.

2.5. Calculation of integrated band intensities

The gas-solid carbonation of calcium hydroxide at low temperature (<30°C) in presence of adsorbed water can be expressed by a global reaction as follows:

\[
\text{Ca(OH)}_2(s) + \text{CO}_2(g) \rightarrow \text{CaCO}_3(s) + \text{H}_2\text{O(\text{v-l})}
\] (1)

Generally, this global reaction is incomplete due to the formation of a protective carbonate layer around the reacting particle which restricts or stops the \text{CO}_2 transfer at the grain or aggregate scale (Montes-Hernández et al., 2010a). In the present study, the integrated band intensities for hydroxyl (-OH), carbonate (\text{CO}_3^{2-}) and \text{H}_2\text{O} functional groups, concerning reaction (1) at an instant \(t\) have been estimated by using a Trapezoidal rule integration. A wavenumber interval and a characteristic continuum have been manually defined to determine the intensity of a given band depending on the initial reactant. For example, in the gas-solid carbonation experiments with \text{Ca(OH)}_2 particles, two continuums have been defined as linear segments over two different spectral ranges, one for the -OH at 3640 cm\(^{-1}\) and \text{H}_2\text{O} at 3450 cm\(^{-1}\) band intensities and the other for the \text{H}_2\text{O} at 1650 cm\(^{-1}\) and \text{CO}_3^{2-} at 1420 cm\(^{-1}\) band intensities (see Figure 2).

2.6. Fitting of the kinetic experimental-calculated data for gas-solid carbonation

Several kinetic models (first-order, pseudo-first-order, second-order, pseudo-second-order, reversible one, irreversible one...) are generally used for fitting kinetic experimental data of sorption and adsorption systems (Ho and McKay, 1999; Ho, 2006). For our experiments, we
have chosen pseudo-second-order model because it was successfully applied in previous studies (Montes-Hernandez and Geraud, 2004; Montes-Hernandez and Rihs, 2006; Montes-Hernandez et al., 2009, 2010a, 2010b, 2012a, 2012b) and can be adequately used to fit experimental data of carbonation process as demonstrated in Montes-Hernandez et al., 2009. This model reproduces a process consisting of a fast mass transfer followed by a second step of slower mass transfer until equilibrium is achieved. It can be written in its differential form as follows:

$$\frac{dA^{CO_3}}{dt} = K_c \left( A^{CO_3}_{max} - A^{CO_3}_t \right)^2$$

(2)

Where $A^{CO_3}_t$ is the integrated band intensity for the carbonate group at a given time, $t$ [minutes], corresponding to carbonation extent; $A^{CO_3}_{max}$ is the maximum extend of carbonation at equilibrium; $K_c$ is the rate constant of Ca(OH)$_2$ carbonation.

The second step (until equilibrium) is interpreted by as a passivation effect due to the formation of a protective carbonate layer (Montes-Hernandez et al., 2012a). In this study, the increase of integrated band intensity with time for the carbonate group ($CO_3^{2-}$), i.e. during gas-solid carbonation process, has been fitted by using a kinetic double-pseudo-second-order model. This model assumes two kinetic regimes due to the presence of two types of reactive surface sites. The integrated form of the double kinetic model is given by the following hyperbolic equation:

$$A^{CO_3}_t = \frac{(A^{CO_3}_{max,1})t}{(t_{1/2,1} + t)} + \frac{(A^{CO_3}_{max,2})t}{(t_{1/2,2} + t)}$$

(3)

Where $A^{CO_3}_t$ is the integrated band intensity for the carbonate group at a given time, $t$ [minutes],
corresponding to carbonation extent; $A^{\text{CO}_3, \text{max}1}$ and $A^{\text{CO}_3, \text{max}2}$ are the maximum extent of carbonation at apparent equilibrium for both kinetic carbonation regimes, respectively; $t_{1/2,1}$ and $t_{1/2,2}$ are the half-carbonation times for both kinetic carbonation regimes, respectively. In other terms, the half-carbonation times represent the times after which half of the maximum of kinetic carbonation regimes (expressed as maximum of integrated band intensities for carbonate group) is obtained. The fitting of kinetics data allow an estimation of these parameters and was performed by a non linear regression by least-squares method. These simple parameters are used in this study to evaluate the kinetic effects of temperature, CO$_2$ pressure and nature of the solid on the gas-solid carbonation process.

The activation energy (Ea, Table 1) of the reaction was calculated assuming an Arrhenius behavior for the initial carbonation rate. We have used 4 points to calculate Ea for carbonation experiments of portlandite (at the temperature of -10°C, 0°C, 10°C and 30°C, for both experiments performed under 1 bar and 2 bar CO$_2$).

3. Results

3.1. Gas-solid carbonation of Ca(OH)$_2$ particles at low temperature (<0°C)

Very few experimental studies have characterized the carbonate formation or CO$_2$ mineralization at the mineral-ice water-CO$_2$ interfaces on Earth and planetary cold-environments (e.g. Antarctic and Mars surface). In our study, several gas-solid reactions carried out in the cryogenic cell coupled to the infrared microscope reveal that carbonate formation or CO$_2$ mineralization is possible at low temperature (-10°C and 0°C) using a simplified analogue Ca(OH)$_2$(mineral)-
water(adsorbed)-CO$_2$(gas) system (see Fig. 3 (c) to (f)). The results displayed in Figure 3 also reveal that the carbonation extent, monitored \textit{in-situ} by an increase of carbonate band intensity at 1420 cm$^{-1}$, is clearly inhibited by a decrease of temperature from 30°C to -10 °C. The increase of integrated band intensity with time for the carbonate group at 1420 cm$^{-1}$ has been successfully fitted by using the kinetic double-pseudo-second-order model. The experimental data and the calculated fits for six experiments are plotted in Figure 4. This “a posteriori” modeling shows the good fits of all the experimental data by such type of kinetic model (correlation coefficient, R close to 1), and confirms the inhibition effect of temperature and the effect of relative humidity on the carbonation extent and kinetic parameters (see also Table 1).

One additional carbonation experiment with Ca(OH)$_2$ particles was carried out at low CO$_2$ pressure (100 mbar) and at moderate temperature (25 °C). For this case, the initial air contained into the cell was previously removed by pumping to secondary vacuum at low temperature (-60°C) as explained in the materials and methods section. Here, a significant carbonation is observed after 4 minutes of Ca(OH)$_2$-CO$_2$ interaction followed by a very slow carbonation step until an apparent spectroscopic equilibrium is possibly reached (about 6h) (see Fig. 5). These experimental data have been also successfully fitted by using the kinetic double-pseudo-second-order model. A last carbonation experiment was performed at a CO$_2$ pressure of 2 bar (at 25 °C) in order to compare with the low CO$_2$ pressure experiments. A significant carbonation was observed during all the experiment (see Fig. 6), which was fitted with the kinetic-pseudo-second order model.

3.2. Gas-solid carbonation of Mg hydroxide

The gas-solid carbonation depends also on the nature of the solid. For this reason one other
powdered material, Mg hydroxide (synthetic brucite), was investigated specifically at higher reactive conditions (25°C and 1bar of CO₂ in presence of air). To form Mg carbonates, the most simple materials as starting reactant are binary oxides or hydroxides in the precursor material. Brucite particles are found to be only slightly carbonated at these T-P₂CO₂ conditions after 5.5h of Mg(OH)_2-CO₂ interaction (see Figure 7). These in-situ infrared measurements clearly reveal that the Mg hydroxide (brucite) is more chemically stable than Ca hydroxide (portlandite) under a CO₂-rich atmosphere at a given relative humidity. In summary, the gas-solid carbonation of Ca and Mg hydroxides depends on the experimental conditions employed (i.e. T, P₂CO₂, relative humidity) and on the intrinsic properties of solid (i.e. hydrophilicity, particle size, specific surface area, and chemical stability).

Finally, a kinetic regime and the maximum carbonation extent at an apparent equilibrium (A_{CO₃,max1} + A_{CO₃,max2}) is successfully determined by using a kinetic double-pseudo-second-order model (see Fig. 7 (c)).

3.3. Gas-solid carbonation of an amorphous calcium silicate hydrate

A last materials, an amorphous calcium silicate hydrate, has been investigated at higher reactive conditions (25°C and 1bar of CO₂ in presence of air) to test the gas-solid carbonation efficiency. The amorphous calcium silicate hydrate, is significantly carbonated via gas-solid carbonation at the above mentioned T-P₂CO₂ conditions after 8h of reaction (see Figure 8), which suggests chemical stability has a significant impact on the efficiency of the carbonation.

Finally, a kinetic regime and the maximum carbonation extent at apparent equilibrium (A_{CO₃,max1} + A_{CO₃,max2}) is also successfully determined by using the kinetic double-pseudo-second-order model (see Fig. 8 (c)).
4. The mechanism of carbonation

All the experiments with the Ca and Mg hydroxides show an increase of the band intensities of carbonates, at low temperature and low pressure. In this study we assume that part of the water initially adsorbed onto Ca(OH)$_2$ particles was partially crystallized by cooling when the temperature is negative (<0°C). The presence of an ice layer limits the access of CO$_2$ molecules to nanopores, and therefore limiting the CO$_2$ access to the local CO$_3^{2-}$ production (CO$_2$(g)+H$_2$O(adsorbed)=>CO$_3^{2-}$+2H$^+$) required to form a carbonate layer around the Ca(OH)$_2$ particles (see also: Montes-Hernandez et al. 2010a). Strictly speaking, the relative humidity is not controlled in our experiments; however, two experiment protocols implying atmospheric vapor have been designed, firstly, direct injection of CO$_2$ gas into the reaction cell initially filled with air, i.e. at lab relative humidity (CO$_2$-air system) and secondly, the injection of CO$_2$ gas after removal of the air by secondary vacuum pumping at low temperature (-60°C) (CO$_2$ system). The difference between these experiments could explain why the carbonation extent decreases when the initial air (contained into the reaction cell) is removed (see comparisons (c) and (d) or (e) and (f) in Fig. 3). We can assume a similar relative humidity of the lab room for all experiments. The relative humidity has clearly an impact on the carbonation efficiency, the experiments without air (very low relative humidity) showing a lower amount of carbonation at low temperature.

The fit of the data by the kinetic model assumes two kinetic regimes, usually due to the presence of two types of reactive surface sites. In our carbonation experiments, the formation of a hydrated carbonate layer around the core of reacting Ca(OH)$_2$ particles produces a complex passivation step, possibly perturbed by three simultaneous physicochemical processes: (1) solid state transformation from hydrated calcium carbonate to calcite and/or from aragonite to calcite, (2) partial expelling of produced molecular water during the carbonation process (see Eq. (1)) and (3)
local acidification by an excess of molecular water in pores or onto surfaces (H₂O(produced) + CO₂(g) -> HCO₃⁻ + H⁺). In summary, the complex kinetic behavior related to gas-solid carbonation of Ca(OH)₂ particles is successfully described applying two kinetic regimes. A schematic representation of this carbonation process is illustrated in Figure 9. The rate of carbonation depends on the access to the nanopores of the material by the CO₂. These pores have to be water-unsaturated to facilitate access of the CO₂ gas to react with the minerals. The pressure has a strong impact on the rate and yield of carbonation. In the case of the low pressure experiments, a two stage kinetic model was shown to fit the data. Experiments revealed a fast carbonation during a short time (stage 1) followed by a slower carbonation (stage 2). The magnitude of carbonate formation is high in stage 1 and lower in stage 2. In the case of the experiments performed at higher CO₂ pressure (2 bar) (fig. 6.c) a two stage reaction is also observed. However, unlike the low pressure experiments, the magnitude of carbonation achieved in stage 2 is quite significant.

For the low pressure experiments, we suspect that the intraparticle diffusion of CO₂, possibly limited by the low gas pressure in the system (100 mbar of CO₂), is the rate limiting step due to the carbonate layer which strongly reduce the diffusion of the gas. This rate limiting step is no more observed at high CO₂ pressure (>20 bar). In this case, the Ca(OH)₂ particles are completely carbonated, leading to the formation of calcite nano-crystals (Montes-Hernandez et al., 2010b). We can assume a correlation between the pressure and the thickness of the layer that transforms to carbonate by gas-solid reaction. The effect of CO₂ pressure observed in explained by the presence of passivation step and the formation of carbonate layer through which CO₂ molecules have to diffuse. Therefore in the case of an uncarbonated material, the effect of CO₂ pressure on the initial reaction rate is expected to be moderate. Although the CO₂ pressure on Mars (about 10
mbar) is lower than CO$_2$ pressures used in our experiments (100 mbar), it is likely that our results can be extrapolated to Martian atmospheric CO$_2$ pressure.

Unfortunately, the gas-solid carbonation mechanism of amorphous calcium silicate hydrate is not elucidated due to its unknown atomic organization. However, we assume that the abundant molecular water adsorbed onto the solid plays a crucial role to start the gas-solid carbonation process at the investigated conditions. The *in-situ* infrared measurements reveal two important insights: (1) The expelling of pre-existent molecular water in/on the solid towards the gas phase during the carbonation process. This is attested by a clear decrease of the stretching and bending band intensities of water (see Fig. 8 (a) and (b)), (2) Similar to carbonation of Ca hydroxide, the formation of calcite and aragonite are mainly identified, the formation of hydrated calcium carbonate being only suspected (see also Montes-Hernandez et al. 2010a)

5. Discussion

Carbonates have been found on Mars in two kinds of geological settings: (i) outcrops of carbonates, identified in the Nili Fossae region (Ehlmann et al., 2008), in the central peak of Leighton crater (Michalski and Niles, 2010) and in the Columbia Hills of Gusev crater (Morris et al., 2010); and (ii) carbonates-bearing dust, identified by the TES instrument (Bandfield et al., 2003) and the phoenix lander (Boynton et al., 2009). In the case of the outcrops from the Columbia Hills and Nili Fossae, carbonates are present as major components (16 to 34 wt % in the case of the Columbia Hills, about 80 % in the case of Nili Fossae), and their derived 17
chemistry is similar to that of carbonates found in Martian meteorites (Mittlefehldt, 1994), i.e. Fe-Mg carbonates. The association of these carbonate outcrops with phyllosilicates advocate for a possible hydrothermal origin of these carbonates, a phenomenon that has been reproduced in laboratory experiments (Golden et al., 2000) and that is observed in some terrestrial hydrothermal systems (Treiman et al., 2002; Brown et al., 2010). However, it is well known that terrestrial alteration of mafic rocks can produce brucite as a primary alteration product (Xiong and Snider Lord, 2008), which should readily transform into carbonate by interaction with the Martian atmosphere, according to our experiments. The observed carbonates outcrops could rather be former outcrops of brucite-rich sedimentary rocks, that were subsequently altered to carbonates by interaction with the atmosphere.

In the case of carbonates observed in the Martian dust, both magnesite (Bandfield et al., 2003) and calcite (Boynton et al., 2009) have been reported, and their typical abundance is below 5 %. Although aqueous formation has received widespread attention for this type of occurrence of carbonates on Mars, we propose gas-solid reaction as a possible formation mechanism. Calcite formation at the dust-CO$_2$ interfaces requires a source of calcium (e.g. Ca binary oxides or an amorphous metastable Ca silicate) possibly coming from volcanic activity (Shaheen et al., 2010), mechanical erosion or extra-Martian particulate matter (including meteorite impacts, interstellar dusts). A large diversity of phyllosilicates and hydrated phyllosilicates was found on the Martian surface (Mustard et al., 2008; Jänchen et al., 2006; Fairén et al., 2009; Murchie et al., 2009; Ehlmann et al., 2011). As we have shown, the presence of molecular water is also required because hydration of the Ca precursor is assumed to be a crucial step prior to the carbonation process. Laboratory studies of Martian analogs suggest that adsorbed water should be present in significant amount within the Martian soil (Pommerol et al., 2009; Beck et al., 2010; Jänchen et
al., 2006) and adsorbed water has been also detected by infrared spectroscopy (Poulet et al., 2009). In addition, the gamma rays and neutrons spectrometers on Mars Odyssey have shown evidence for the presence of water in the first meter of the martian subsurface (Feldman et al., 2004). A simplified scenario for calcite formation at the dust-CO$_2$ interfaces and its natural deposition on the soil is schematically illustrated in Fig. 10. In this scenario we assume that the precursor, a calcium hydroxide with adsorbed water, is produced by atmospheric alteration of volcanic CaO particles in the atmosphere. Reactant minerals such as portlandite could be difficult to detect on Mars by reflectance spectroscopy due to the carbonate layer around the calcium hydroxide. In the case of hydromagnesite, the presence of brucite is required somewhere on Mars, which would be subsequently transformed to carbonates, eroded, and transported. As we stated earlier, brucite should form in association with phyllosilicates during the aqueous alteration of mafic rocks.

The efficiency of carbonates synthesis on Mars by gas-solid reaction will depend on the mineral substrate (as we showed, brucite, portlandite and larnite have distinct synthesis kinetics), the local temperature, the atmospheric humidity, and likely the atmospheric pressure (which can substantially vary with season as well as with topography). Even at temperatures below the frost point, carbonates synthesis can occur by gas-solid reaction, on a daily timescale (table 1). On Mars, the water vapor pressure is low (P$_{H_2O}$ about 10 Pa) and the frost point is depressed with regard to that on Earth. Given the present knowledge of the water vapor surface pressure, a typical value of 200 K is found for the frost point on the Martian surface (Schorghofer and Aharonson., 2005). Such temperature typically corresponds to seasonal average around 60° in latitude.

The relative humidity on Mars fluctuates on a daily basis. At the Phoenix landing site (Smith P.H. 19
et al., 2009) it is measured around 5% during Martian day time, close to saturation early night and saturating at the end of the night. Carbonate synthesis will be accelerated by a high atmospheric humidity, which can occur during the warmer season. TES instrument on Mars Global Surveyor has water vapor evolution during 2 martian years, and the maximum was found during midsummer in the northern hemisphere with 100 pr-µm (Smith M.D., 2002,2004). The maximum water vapor measured by Mars Express instruments (OMEGA and SPICAM) is found during midsummer, around 60 pr-µm content. This maximum is observed at latitude 75-80°N and longitudes 210-240°E (Fouchet et al., 2007; Fedorova et al., 2006; Melchiorri et al.,2007)), an area is close to Phoenix landing site (latitude 68°N and longitude 233°E).

Current Global Circulation Models (GCM) of Mars can be used to determine the optimal locations and times for the gas-solid synthesis of carbonates. Simulations with Mars Climate Database (Forget et al., 1999, 2006) estimated high relative humidity (around 70%) and temperatures close to -20°C during mid summer (Ls =120°) in the Phoenix landing site area (at 12 a.m). These conditions are sufficient to initiate the carbonation reaction according to our experiments, and carbonates were observed in the Phoenix soil (Smith et al., 2009)

Mars is not the only extra-terrestrial body where carbonates have been detected, this is also the case of Ceres, the largest asteroid in the main belt. Its shape is close to hydrostatic equilibrium and its bulk density suggests the presence of ice in its interior (Thomas et al., 2005). The surface of Ceres shows a well-resolved 3-µm absorption band, which interpretation has been debated (Lebofsky et al., 1981; Vernazza et al., 2005; Rivkin et al., 2006; Rivkin et al., 2011; Beck et al., 2011). In a recent study, Milliken and Rivkin (2009) combined NIR and MIR observations of Ceres' surface and successfully modeled both spectral regions with a combination
of brucite, carbonate and a Fe-rich phyllosilicate. Such a mineralogical assemblage was explained by aqueous alteration of mafic silicates in the presence of CO$_2$, by analogy with the processes inferred from the mineralogy of hydrated meteorites that can present a significant amount of carbonates (Zolensky et al., 2002). If brucite is rare in the mineralogy of hydrated chondrites, it is a common product of aqueous alteration of terrestrial rocks. The condition of brucite formation is specific in terms of T, pH and pO$_2$, and source rock. If the formation of carbonate by reaction of brucite with water is possible, gas-solid reaction cannot be excluded. This mechanism could occur at some depth in the asteroid body, where CO$_2$ pressure can build-up. However, because of the low temperature at the surface of Ceres, long timescales are expected for such a process. Further consideration would require an accurate knowledge of the kinetics of the gas-solid carbonation.

Finally, the carbonate synthesis mechanism that we described is certainly active on Earth, where carbonate minerals played an important role in the planet evolution. Many studies are available about carbonate reactivity and synthesis in liquid-water but information on its behavior at sub-zero temperatures (for example solubility in frozen water) are sparse. The results we obtained reveal that gas-solid carbonation can occur at sub-zero temperature, in the presence of gaseous CO$_2$ and H$_2$O. These conditions are present on Earth in arctic regions and in the upper atmosphere. This mechanism can thus occur on the availability of the adequate precursor.

The presence of oxygen isotope anomalies in carbonates from terrestrial aerosols (Shaheen et al., 2010) suggests a carbonation by exchange with ozone. Such a result suggests a possible formation of carbonate by chemical reaction in the upper atmosphere, from a CaO precursor. We can propose hydration of CaO$_{(s)}$ by H$_2$O$_{(g)}$, and successive reaction of Ca(OH)$_{2(s)}$.
Calcium carbonate and carbonate hydrates have been found in arctic ice (Dieckmann et al., 2008; Sala et al. 2008). The formation mechanism of these carbonates is a matter of active research, since it could provide a major CO$_2$ sequestration process. Hydrous carbonates (for instance ikaite) have been proposed to originate by precipitation during sea-ice formation, as suggested by thermodynamical calculations. Anhydrous carbonates can have an origin as primary aerosols, with a synthesis mechanism possibly similar to the one described in the previous paragraph. In addition, in situ gas-solid formation is possible, depending on the availability of an adequate precursor (as we showed here, an Ca or Mg hydroxides, or Ca-rich amorphous silicates).

6. Conclusion

In this study, we designed an original experimental method to form carbonates via gas-solid reaction in presence of adsorbed water. We used an infrared microscope coupled to a cryogenic reaction cell (IR-CryoCell setup) to investigate this process with 3 different carbonate precursors (Ca hydroxide (portlandite), Mg hydroxide (brucite), and an amorphous calcium silicate hydrate). We demonstrated for the first time that calcium carbonate can be formed at low temperature (<0°C) via gas solid carbonation of Ca hydroxide. Both amorphous Ca silicate hydrate and Ca hydroxide were significantly carbonated at the investigated T-P$_{CO2}$ conditions. Conversely, only a very slight gas-solid carbonation of Mg hydroxide particles was detected by IR spectroscopy. We extracted the kinetic parameters of the reaction from our measured carbonation curves, following a kinetic double-pseudo-second-order model. From these results we can clearly state that the conditions for gas-solid carbonation exist on Mars, and that this process could be the source of...
the detected Ca and Mg carbonates found in the Martian dust and soil. These carbonates can be synthesized from a brucite precursor (a common hydrothermal product), from volcanic derived aerosols, as well as from extraterrestrial dust. This mechanism should be considered in future global modeling of the carbon cycle of the red planet, and might also be active in cold terrestrial deserts.
