## Abstract

Comparison of glacially derived clastic inputs in high altitude proglacial lake Bramant (Western French Alps) with measured North Atlantic Oscillation winter (NAO<sub>w</sub>) index reveals an inverse correlation between AD 1884 and 1968 at the pluridecadal timescale (20–25 years). This reflects periodical variations in snow accumulation over Lake Bramant catchment area partly influencing the glacier mass balance in the watershed. Further comparisons with reconstructed NAO<sub>w</sub> index since AD 1500 highlight spatial and temporal variations of the pluridecadal NAO<sub>w</sub> influence on this alpine climate, especially at the end of the ‘Little Ice Age’. In addition, wavelet analysis of continuous proxies of clastic sedimentation over the last 4150 years indicates significant pluridecadal variability at frequencies compatible with the NAO (30 years), while periods centered at 60–70 years could also be linked to the North Atlantic Ocean–atmosphere internal variability (Atlantic Multidecadal Oscillation (AMO)). The influence of the North Atlantic deep water production on the regional alpine climate is also suggested by a significant 550 yr cycle of clastic inputs since 2800 cal. BP. Coupling between the North Atlantic Ocean and the atmosphere seems therefore to play a fundamental role on glacier mass balance and climate during the late Holocene in the western Alps.

## Keywords

AMO, ITRAX, late Holocene, NAO, proglacial lake, wavelet, Western French Alps

## Introduction

The North Atlantic area is often recognized to have an important impact on the European climate. A large part of the winter atmospheric circulation variability in the North Atlantic region is associated with the North Atlantic Oscillation (NAO) (Hurrell, 1995) which is coupled to the North Atlantic sea surface temperature (SST) through latent heat fluxes (Rodwell et al., 1999). The NAO influences the underlying ocean and the surrounding continent. This major climate oscillation is described with an index defined as the difference between the standardized winter sea level pressure (SLP) at the Azores (High) and Iceland (Low) (Appenzeller et al., 1998; Hurrell, 1995). The SLP difference drives surface winds and winter storms from west to east across the North Atlantic and fluctuates at various timescales (e.g. Appenzeller et al., 1998; Cook et al., 1998; Hurrell and van Loon, 1997). During positive NAO phases (enhanced Azores High and enhanced Iceland Low, NAO+), westerly flow is enhanced and moves relatively warm and moist maritime air over much of northwestern Europe while enhanced northerly winds over Greenland and northeastern Canada result in a drop in temperature over the northwestern Atlantic (Hurrell 1995). Opposite patterns of temperature and precipitation are typically observed in western Europe during negative phases of the NAO (reduced Azores High and reduced Iceland Low, NAO–) and enhanced winter precipitations in the NW Alps (Beniston, 1997; Chapron et al. 2002).

High altitude alpine environments are particularly sensitive to climate changes. Several studies have already shown that European alpine glacier mass balance is influenced by NAO<sub>w</sub> phases (e.g. Reichert et al., 2001; Six et al., 2001). Proglacial lacustrine sediments are often used to reconstruct paleoclimates and paleoenvironments since glacier fluctuations, directly linked to

winter precipitation and summer temperature, may be recorded in detrital sedimentary sequence accumulated in the basin (e.g. Chapron et al., 2007; Dahl et al., 2003; Guyard et al., 2007a; Nee-mann and Niessen, 1994; Nesje, 2009). As bedrock erosion rate increases with glacier size and thickness, fluctuations in the amount of silt- and clay-sized mineral fraction provide a reliable record of glacier activity. Particularly, time series analysis methods of continuous high-resolution sedimentary records are useful tools to decipher decadal to centennial climatic oscillations and to identify mechanisms and relationships between different components of the climate system (Chapman and Shackleton, 2000; Debret et al., 2009; Wanner et al., 2011).

This paper describes clastic supply fluctuations in relation to glacial activity from finely laminated sediments retrieved in high altitude proglacial Lake Bramant (Grandes Rousses Massif, Western French Alps; Figure 1). We present detrital input periodicities and their temporal evolution using continuous wavelet analysis

and global spectrum in order to examine large-scale climatic mechanisms influencing the glacial dynamic and resulting proglacial sedimentation over the last 4150 cal. BP.

## Setting

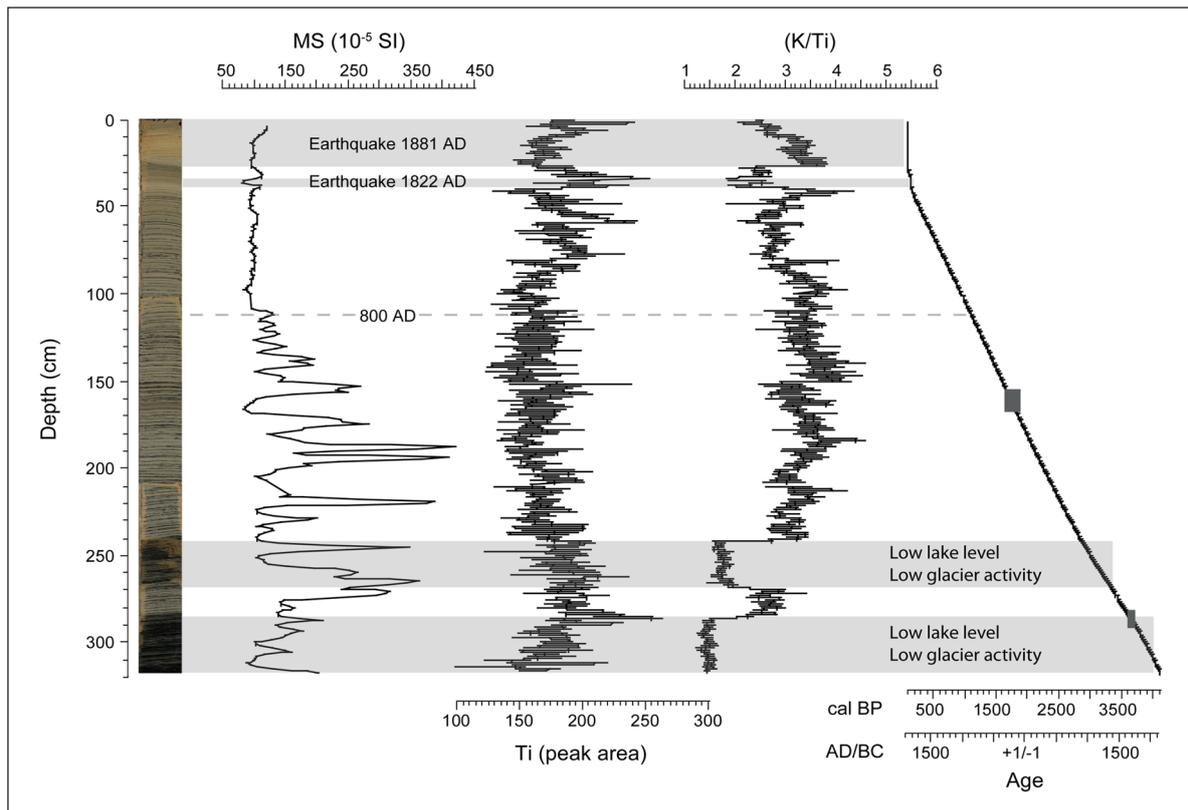

The large majority (81%) of glaciers in the Alps are small (<0.5 km<sup>2</sup>) (Zemp, 2006). The St. Sorlin glacier (3 km<sup>2</sup>) located on the northern part of the Grandes Rousses Massif (45°7'N, 6°6'E) between 2650 m a.s.l. and 3400 m a.s.l. (Figure 1) is sensitive to climate changes (Vincent, 2002) and generally considered as representative for the NW alpine region (Six et al., 2001; Vincent, 2002). In the glacial Bramant valley, Lake Bramant (2448 m a.s.l.) is the third and lowermost lake of a chain of high altitude small proglacial lakes and drains the Côte Blanc glacier and only the western part of the St. Sorlin glacier, because of a glacial diffluence on a bedrock knob (Figure 1). Glacial meltwaters are naturally filtered by the upper proglacial lakes (Lake Tournant and Lake Blanc), which successively retain the coarser particles. Today, the outlet of Lake Blanc constitutes the main tributary of Lake Bramant. As such, clastic inputs originating from glacial melting are mainly characterized by fine detritic elements ranging from fine sand to fine silts (Guyard et al., 2007a).

Sediment cores retrieved from the Lake Bramant deep basin contain two dark and organic-rich intervals reflecting lower lake-level periods from 4150 to 3600 cal. BP and from 3300 to 2850 cal. BP resulting from reduced glacier activity in the drainage basin (Guyard et al., 2007a; Figures 2 and 3). The onset of lighter clastic proglacial sediments and higher lake level between 3600–3300 cal. BP and since 2850 cal. BP indicate periods of higher glacier activity associated with an upstream diffluence that acts as an on–off switch of glacial meltwater supply into the Bramant Valley (Chapron et al., 2008; Guyard et al., 2007a). Sediments are finely laminated throughout the sequence (Figure 2). Coarser and darker laminations are characterized by lower fine detritic element contents and higher organic matter contents. The thicknesses of these darker laminations are variable.

## Materials and methods

### Sedimentological analyses and composite sequences

The piston (BRA03) and gravity (BRA03-1) cores were run through an ITRAX core Scanner (Mo tube) at INRS-ETE (Quebec city) to detect relative variations of geochemical elements from Al to U (e.g. Croudace et al., 2006; Guyard et al., 2011) in order to

**Figure 2.** General simplified lithostratigraphy of the core BRA03 and clastic fluctuations (Ti and K/Ti) since 4150 cal. BP. MS: volumetric magnetic susceptibility. The age–depth relationship is detailed in Guyard et al. (2007a). The dark grey highlights periods of local or regional mining activity. The thin dotted line illustrates a major sedimentological change at AD 800 (see text for details).

investigate fluctuations of glacially derived clastic inputs. Analyses were performed at a downcore resolution of 300  $\mu\text{m}$  for BRA03-1 (corresponding to about 12 data points per year on average; irradiation during 10 s) and 100  $\mu\text{m}$  for BRA03 (corresponding to about 6 data points per year; irradiation during 1 s). We used the ratio K/Ti as a proxy for glacial flour since K is generally associated with fine detrital clay (Croudace et al., 2006) and Ti fluctuations for global detritic inputs (i.e. not necessarily glacially derived). Volumetric magnetic susceptibility was measured at 1 cm intervals on u-channel samples at the University of Florida.

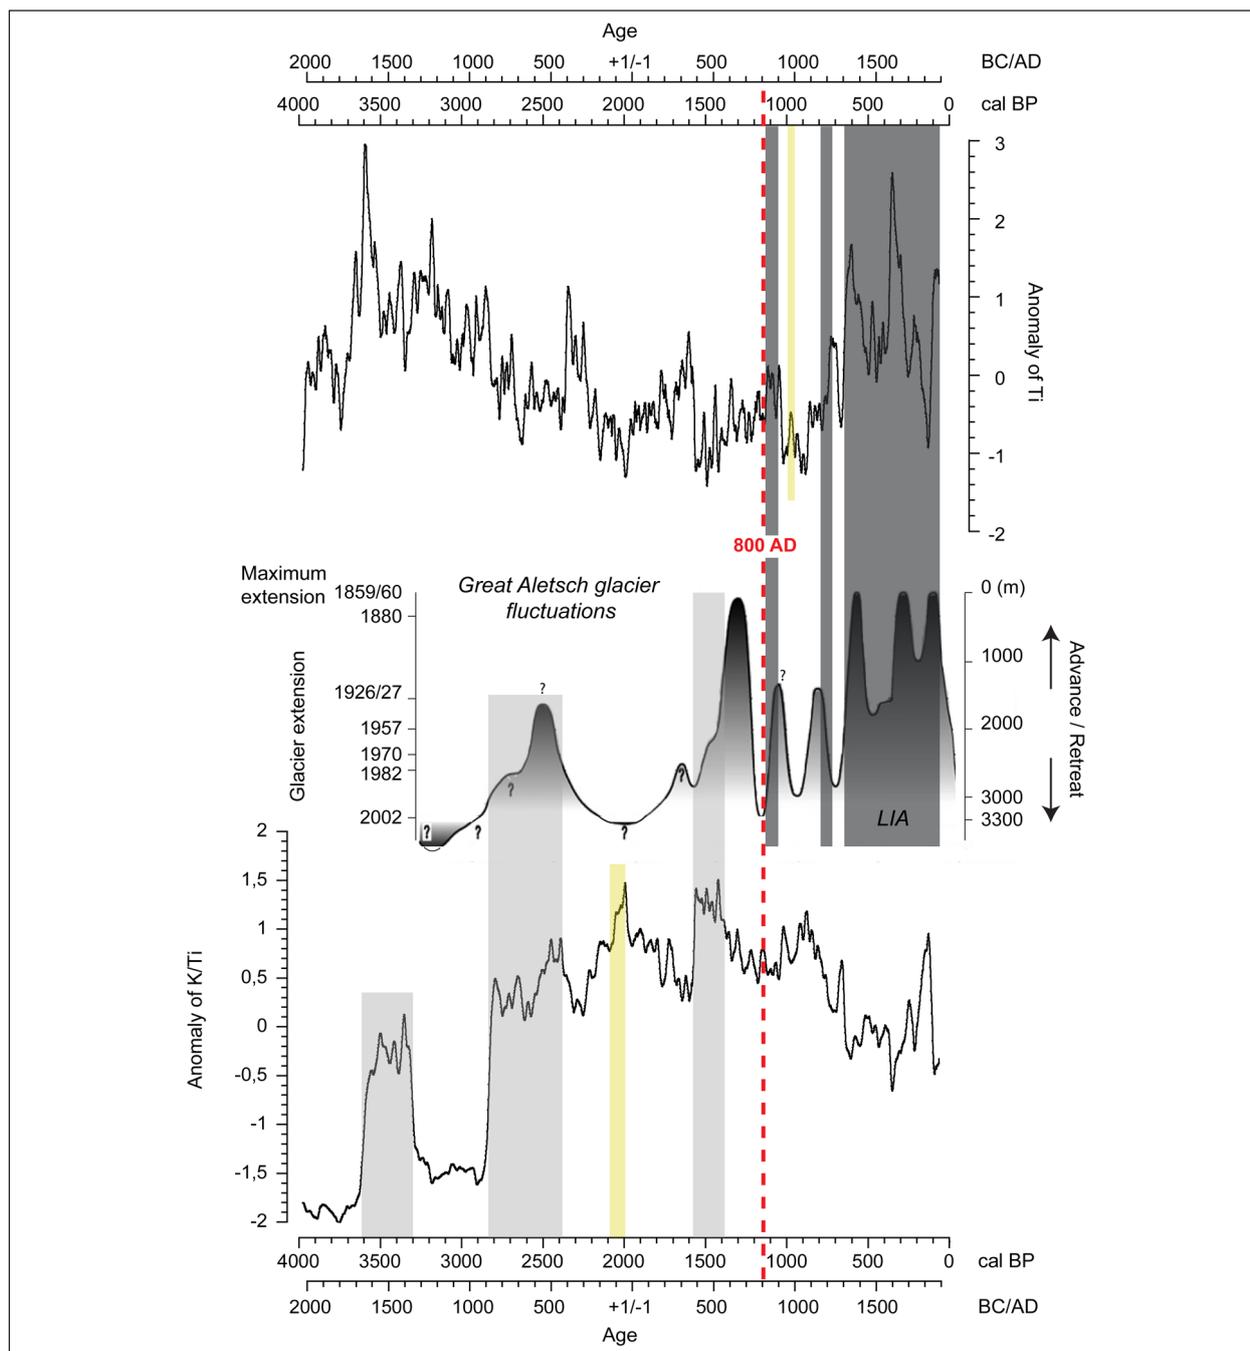

The age–depth model was previously established and is based on the combination of  $^{137}\text{Cs}$ ,  $^{241}\text{Am}$  and radiocarbon dating, varve counting, the recognition of historical natural events and on the regional or local mining activity records (Carozza et al., 2010; Chapron et al., 2008; Guyard et al., 2007a). Cores BRA03-1 and BRA03 comprise an AD 1884–1968 and a  $\sim$ 4150–100 cal. BP sedimentary record, respectively. The composite sequence for short core BRA03-1 (Figure 4) was constructed after removing the top of the slump associated with the nearby AD 1881 Allemond earthquake and 2 cm thick flood deposits dated at AD 1904–1905 and 1908–1910, likely related to major glacier retreat (Guyard et al., 2007a, 2007b). In a similar manner, the composite sequence of BRA03 was established after removing the base of the slump associated with the 1881 Allemond earthquake and the turbidite triggered by the AD 1822 Chautagne earthquake (Figure 2; Guyard et al., 2007a, 2007b). Both cores were retrieved at the same coring site (Figure 1) and the spectral signal obtained as discussed below can therefore be compared.

#### Wavelet analysis

The clastic sedimentary records were investigated using the continuous wavelet transformation, which is a useful method to analyze complex non-stationary time series (Torrence and Compo,

1998; Witt and Schumann, 2005). In this study, the Morlet wavelet (a Gaussian-modulated sine wave) was used for the continuous wavelet transform. The region of the wavelet spectrum in which edge effects becomes significant is known as the cone of influence (COI), defined as the e-folding time for the autocorrelation of wavelet power at each scale. The wavelet power spectral density was calculated for each parameter following Torrence and Compo (1998) and the interval of 95% confidence is marked by black thin contours. We used red noise background spectrum (increasing power with decreasing frequency) to determine the significant levels of the global wavelet power spectrum. Raw data of clastic fluctuations (reflected by K/Ti and Ti variations) was first transformed in temporal data and then resampled every year by linear interpolation. A low pass filter was applied to the annual data to attenuate the very high frequencies before performing statistical analyses on lower frequencies (e.g. Boucher et al., 2011; Chapron et al., 2002; Six et al., 2001). The power of these lower frequencies already present in the raw data was thus increased by the filtering process owing to the attenuation of the high frequencies (e.g. noise). For short timescales (e.g. the instrumental period), a low pass filter (5- to 11-year running mean) was applied to reduce the ‘noise’ of small-scale and transient meteorological phenomena not related to large-scale climate variability. For longer timescales, centennial cycles of clastic fluctuations were determined after low pass filtering (100-year running mean) in order to study their long-term variations. To focus on pluridecadal periodicities, we removed the long-term variation by subtracting the 100-years smoothed time series from the annual data following Chapron et al. (2002). Once again, a low pass filter (5- to 11-year running mean) was then applied to attenuate the influence of the high frequencies on the signal. All data were normalized to the standard deviation.

Cross wavelet transforms (Grinsted et al., 2004) were also constructed to examine the variability of the relationship between

**Figure 3.** Comparison between proglacial Lake Bramant clastic sedimentation and the Great Aletsch glacier fluctuations. Modified after Holzhauser et al. (2005). Light and dark grey intervals highlight the glacial advance periods correlated with higher K/Ti and Ti inputs, respectively. The red dashed line marks the sedimentation change c. AD 800. The glacial activity fluctuations from AD 800 are reflected by Ti variations. The yellow zones illustrate higher clastic inputs in Lake Bramant that are correlated with clastic fluctuations in Lake Le Bourget record (Debret et al., 2010). LIA: 'Little Ice Age'. K/Ti and Ti anomalies were smoothed by a 30-year running mean (colour figure available online).

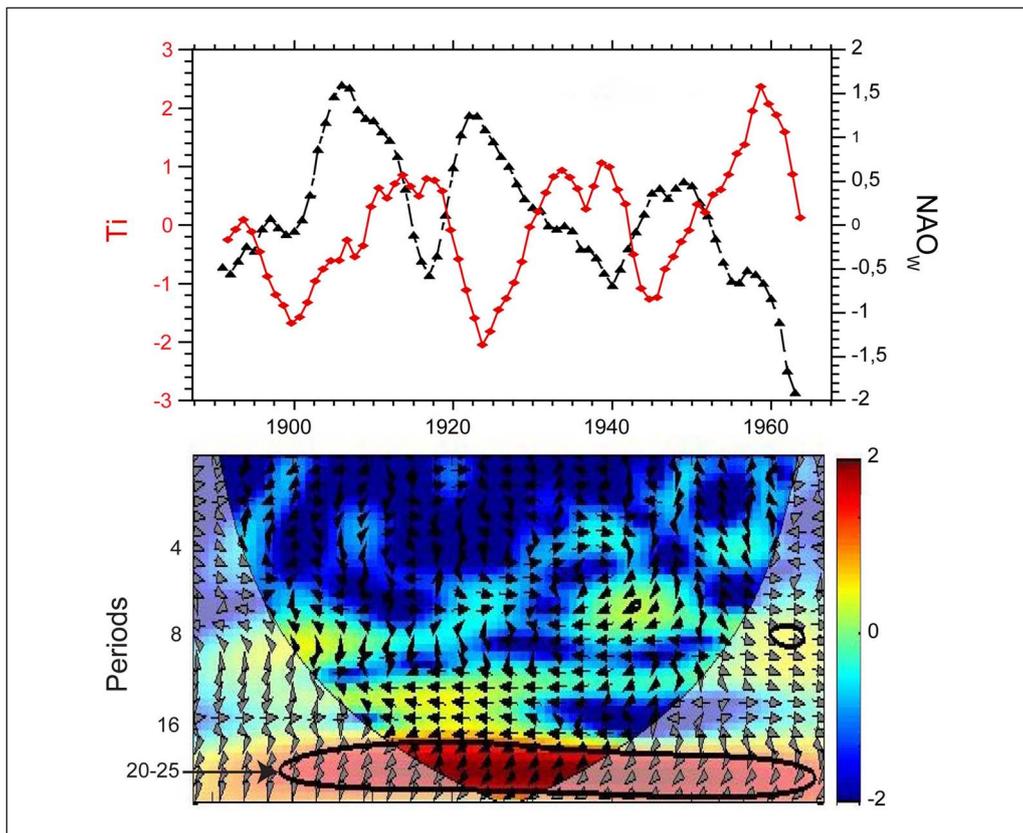

the NAO and clastic fluctuations since AD 1500. The analysis of the covariance of the two time series and the 95% confidence level follow the work of Torrence and Compo (1998). The Morlet wavelet cross-spectra permit to depict the features common to the climatic indices and NAO index and to highlight temporal variations in their relationship. If the coherence between two series is high, the arrows in the coherence spectrum (Figures 4 and 5) show the phase between the time series: arrows at horizontal right (left) indicate that both time series are in phase (anti-phase) and imply a linear relationship. As the influence of the NAO on glacier fluctuations is most pronounced during winter (e.g. Nesje et al., 2000), only the winter NAO index ( $NAO_w$ ) (December–February) is considered here for comparison. Furthermore, since the

NAO and climate indices as well as the glacier fluctuations are highly variable on the annual timescale (e.g. Six et al., 2001), the records were smoothed (5- to 11-year running mean) to remove the annual variability.

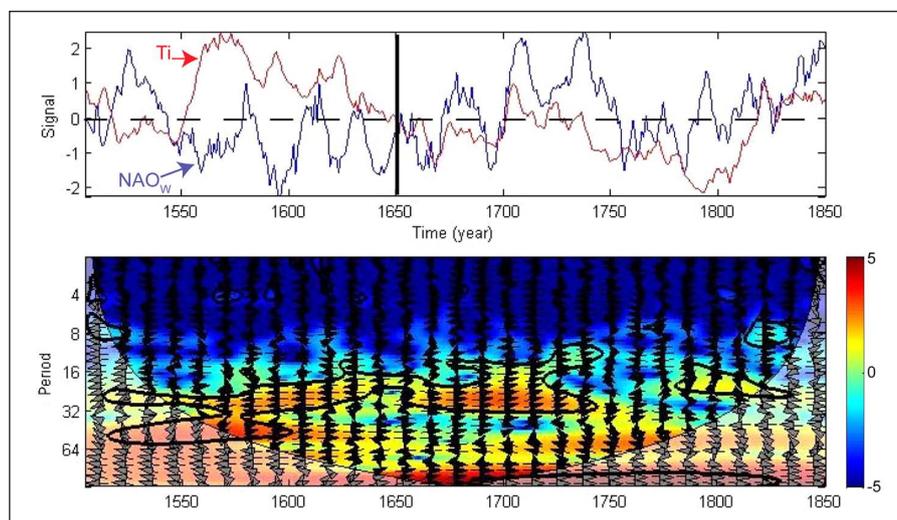

## Results and discussion

### Glacier fluctuations

The increase of the ratio K/Ti observed between 1650 and 1350 BC (Figure 3) reflects higher erosion resulting from stronger glacier activity in the catchment. This is in agreement with a wetter and colder period documented by a high lake-level period between 1600 and 1200 BC in west-central Europe (e.g. Holzhauser et al.,

**Figure 4.** NAO winter index (Hurrell, 1995) and Ti fluctuations between AD 1888 and 1965. Both curves are normalized and smoothed by a 5-year running mean to reveal a common signal between both variables by reducing the annual to pluriannual 'noise'. The lower panel illustrates the results of cross wavelet analysis results which reveal a significant anti-phase relationship between both time series on multidecadal timescales (20–25 years) (sampling period: 1 year). The lighter area denotes the COI and black contours represent the 95% confidence level based on a red-noise background. When the coherence between the two series is high, arrows at horizontal left (right) in the coherence spectrum indicate that both time series are in anti-phase (phase) (colour figure available online).

**Figure 5.** Reconstructed NAO winter index (DJF) (Luterbacher et al., 2002) and Ti fluctuations between AD 1500 and 1850. Both curves are normalized and smoothed by a 11-year running mean. The lower panel illustrates the results of cross wavelet analysis which reveal a significant and variable relationship between both time series on multidecadal timescales (20–25 years) (sampling period: 1 year). The lighter area denotes the COI and black contours represent the 95% confidence level based on a red-noise background. When the coherence between the two series is high, the arrows at horizontal left (right) in the coherence spectrum indicate that both time series are in anti-phase (phase) (colour figure available online).

2005). The increase of the K/Ti ratio observed between 900–450 BC and AD 350–550 (Figure 3) is also interpreted as an increase in glacial activity and glacial erosion. These two periods correspond to late-Holocene cold events described in Wanner et al. (2011) and are relatively synchronous to glacial advances in the Swiss

Alps (Holzhauser et al., 2005) (Figure 3). Indeed, probably because of its small size, St. Sorlin glacier may respond to climatic forcing slightly before more continental European glaciers, such as the much larger Aletsch glacier (Deroin and Condom, 2007; Holzhauser et al., 2005). The increase of clastic inputs

observed around BC 150 is also consistent with clastic fluctuations in the Lake Le Bourget record, indicating enhanced Rhone River flooding activity in large alpine valleys (Chapron et al., 2005; Debret et al., 2010).

From ~ AD 800, a major lithological change in the sedimentation is reflected by slightly darker sediments, a drop in magnetic susceptibility values and a decreasing trend of K/Ti content (Figures 2 and 3), as well as by a rise of measured gamma density values and by less sorted and slightly coarser silty sediments (Guyard et al., 2007a). This mineralogical and/or grain size change is probably associated with a sedimentary source variation and could result from sedimentary filling of the uppermost proglacial and shallow Lake Tournant (Figure 1) following the regional alpine glacier advance (e.g. Holzhauser et al., 2005) and the associated late-Holocene cold event (Wanner et al., 2011). This is consistent with a similar change in the sedimentary infill observed in Lake Tournant at the end of the LIA (Shaw et al., 1958). As a result, the glacial activity fluctuations from AD 800 become better recorded in Lake Bramant by Ti variations which probably reflect coarser grain size and indicate glacial advance between AD 800 and 900, around AD 1200 and since AD 1350 (Figure 3). These periods are synchronous with glacial advances in the Swiss Alps (Holzhauser et al., 2005; Figure 3), with higher lake level periods in Western Europe (Magny, 2004) and with clastic fluctuations in Lake Le Bourget record (Chapron et al., 2002, 2005; Debret et al., 2010).

The LIA was dated south of the Massif between AD 1350 and 1880 and resulted in the lowering of glacial equilibrium line altitude (ELA) in the western French Alps and intense flooding in the alpine valleys (Chapron et al., 2007; Vincent et al., 2005). Maximum Ti inputs around AD 1350, between AD 1580 and 1620 and AD 1820–1850 (Figure 3) are consistent with LIA maximum glacial expansion in the Alps (e.g. Nussbaumer et al., 2007). Significant glacial fluctuations also occurred during the 18th century and are indicated by darker sediments with lower Ti contents, suggesting an elevation of the ELA in the drainage basin (reduced glacier activity). This period is also reflected by more organic sediments in proglacial Lake Blanc Huez, located in the southern part of the Massif (Chapron et al., 2007).

#### *Impact of the NAO on Lake Bramant recent sedimentation*

Direct correlation between the NAO<sub>w</sub> index measured since 1880 (Hurrell, 1995) and glacial clastic inputs over Lake Bramant watershed is weak, reflecting the relatively low relationship between alpine glacier mass balance and NAO fluctuations at the annual timescale (see also Imhof et al., 2012; Marzeion and Nesje, 2012; Six et al., 2001). Nevertheless, by reducing this annual 'noise' (running mean), the comparison of the time series revealed an anticorrelation between the glacial meltwater supply (reflected by Ti fluctuations) and the measured NAO<sub>w</sub> index at decadal timescales (Figure 4). This inverse relationship thus suggests oscillations in snow precipitation and accumulation during late autumn and winter over Lake Bramant catchment area influencing the St. Sorlin and Côte Blanc glacier mass balances and erosive processes over the catchment at decadal timescales (enhanced precipitation and snow accumulation during NAO- phases). In addition, the cross wavelet analysis confirms a relatively strong anti-phase relationship between both time series at the multidecadal timescales (20–25 years), while multiannual variability appears to be less correlated to the NAO (Figure 4). This reflects the complexity of glacial systems and dynamics. Moreover, the 20–25 year periodicity is consistent with fluctuations of the NAO<sub>w</sub> index at decadal timescales (e.g. Cook et al., 1998; Rogers, 1984).

NAO+ phases are generally correlated with anomalously low precipitation and higher than average temperatures during the

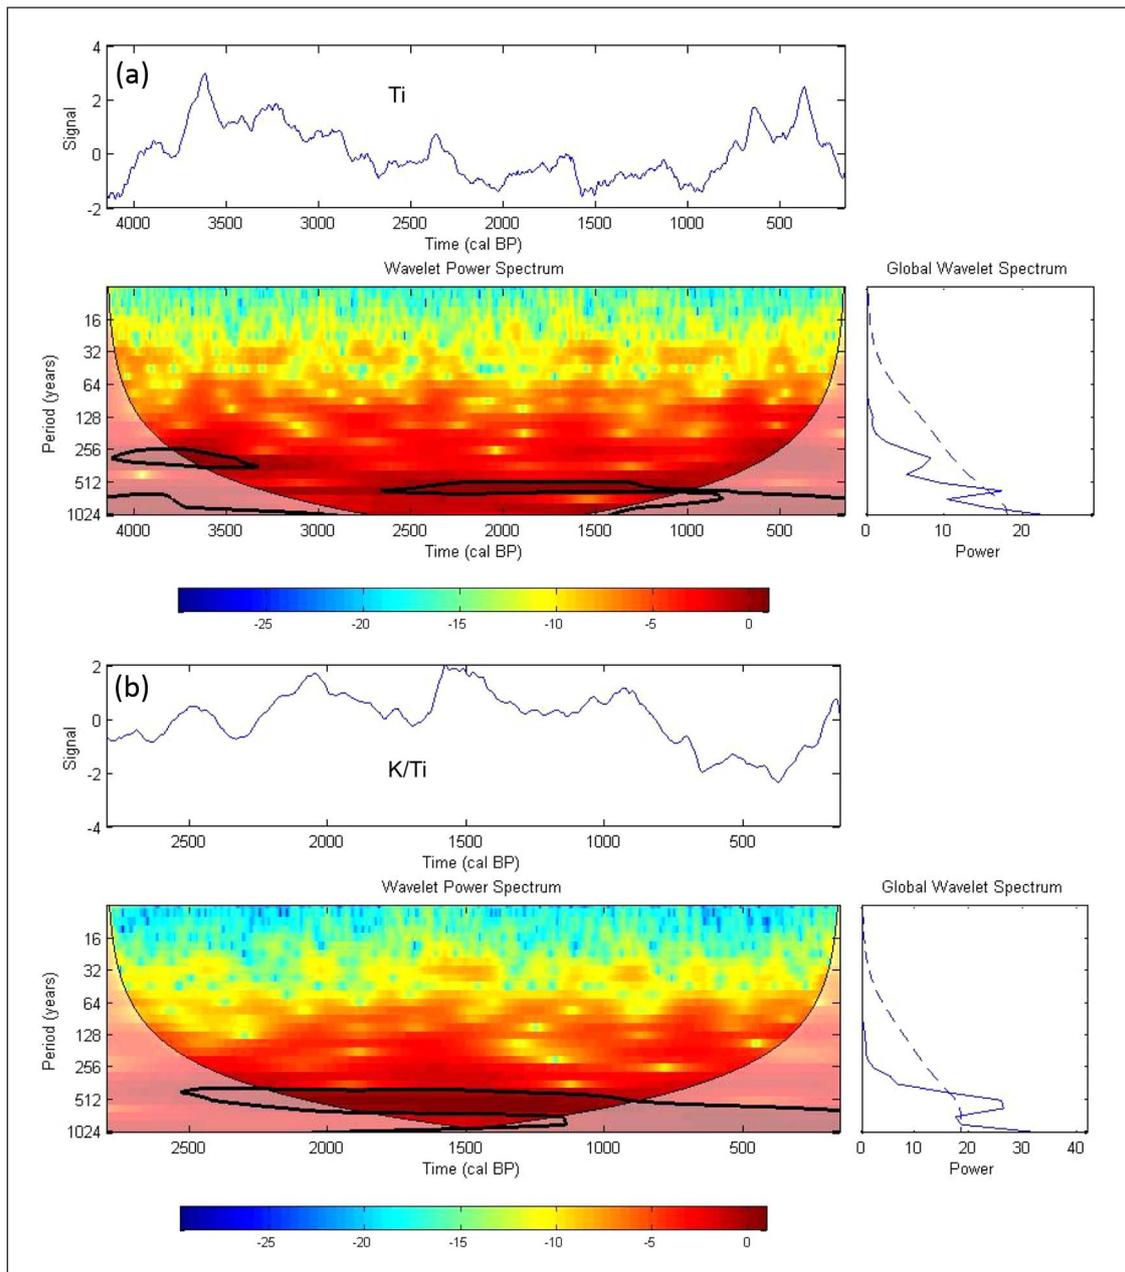

winter in southern and much of Central Europe, including the Alps (Beniston and Jungo, 2002; Wanner et al., 1997), while heavier-than-average precipitations are observed over northern Europe and Scandinavia (Hurrell and van Loon, 1997; Selten et al., 1999). These conditions result in reduced winter accumulation and lower mass balance (ELA elevation) of European alpine glaciers and thus, after a certain delay, to their retreat (Nesje et al., 2000; Reichert et al., 2001; Six et al., 2001). Six et al. (2001) found that the annual NAO index explains at best 36% of the St. Sorlin annual mass balance variance ( $r = -0.6$ ) while Reichert et al. (2001) found an inverse relationship between decadal variations in the NAO<sub>w</sub> index and the Rhone Glacier (Switzerland) mass balance ( $r = -0.64$ ) using a modeling approach.

On the other hand, the NAO influence on mass balance of Scandinavian glaciers is positive and more pronounced than in the alpine region (Imhof et al., 2012; Six et al., 2001), probably because the dynamic of Scandinavian maritime glaciers are mostly driven by winter precipitations originating from the North Atlantic area, while the alpine glaciers are more sensitive to summer temperature (which is less influenced by NAO) (Reichert et al., 2001; Steiner et al., 2008). During the 20th century, glacier fluctuations observed in the alpine region are essentially controlled by mean summer temperature (Vincent, 2002). Furthermore, as the Alps are situated in the transition zone between northern Europe and southern Europe, the NAO influence on European alpine climate is more complex and sometimes equivocal (Casty et al., 2005; Scherrer et al., 2004).

#### *Impact of the NAO during the LIA*

Further comparison between clastic inputs and reconstructed NAO<sub>w</sub> index (Luterbacher et al., 2002) highlights a negative correlation between AD 1500 and 1650 similar to that during the 20th century followed by a positive correlation between AD 1650 and 1850. This could indicate that the multidecadal NAO influence (20–25 years) was not constant during the LIA, as also shown by the cross wavelet results (Figure 5). These results may thus reflect the non-stationarity and non-linearity characteristics of large-scale phenomena on alpine glacier mass balance and climate.

The glacier variations in the European alpine area are asynchronous with the glacial fluctuations in Scandinavia partly because of the multidecadal trends in the north–south dipole NAO pattern (e.g. Imhof et al., 2012; Nesje and Dahl, 2003). The negative and weaker correlation (compared with Scandinavian glaciers) between NAO<sub>w</sub> index and Ti inputs in Lake Bramant probably indicate that decreasing temperature may be the dominating factor responsible for the LIA glacier advances in the Grandes Rousses massif until AD 1650. This is in agreement with summer temperature reconstruction over the Alps (Büntgen et al., 2006) indicating a prolonged cooling during AD 1350–1700. The following positive correlation observed between AD 1700 and 1850 could reflect hemispheric-scale atmospheric circulation reorganizations during the last part of the LIA and a southern shift of westerlies, since an increase of winter precipitation would be responsible for glacier advance in western Scandinavian in the early 18th century (Nesje and Dahl, 2003; Nesje et al., 2008). A higher influence of winter precipitation during the last LIA phase of alpine glacier advance was also proposed by Vincent et al. (2005), who demonstrated an increase of at least 25% of winter precipitation between AD 1760 and 1850. Nevertheless, as the analysis of regional reconstructed precipitation variability over the last 500 years reveals major non-stationarities with large-scale circulation patterns (e.g. Pauling et al., 2006), other modes of atmospheric circulation may thus have controlled Alpine climate variability through the recent past, as proposed by Casty et al. (2005).

**Figure 6.** Low frequency variability of clastic supply. (a) Ti fluctuations between 4100 and 100 cal. BP and (b) K/Ti between 2850 and 100 cal. BP. Both time series are smoothed by a 100-year running mean. Sampling period: 4 years. The lighter area denotes the COI and black contours represent the 95% confidence level based on a red-noise background (colour figure available online).

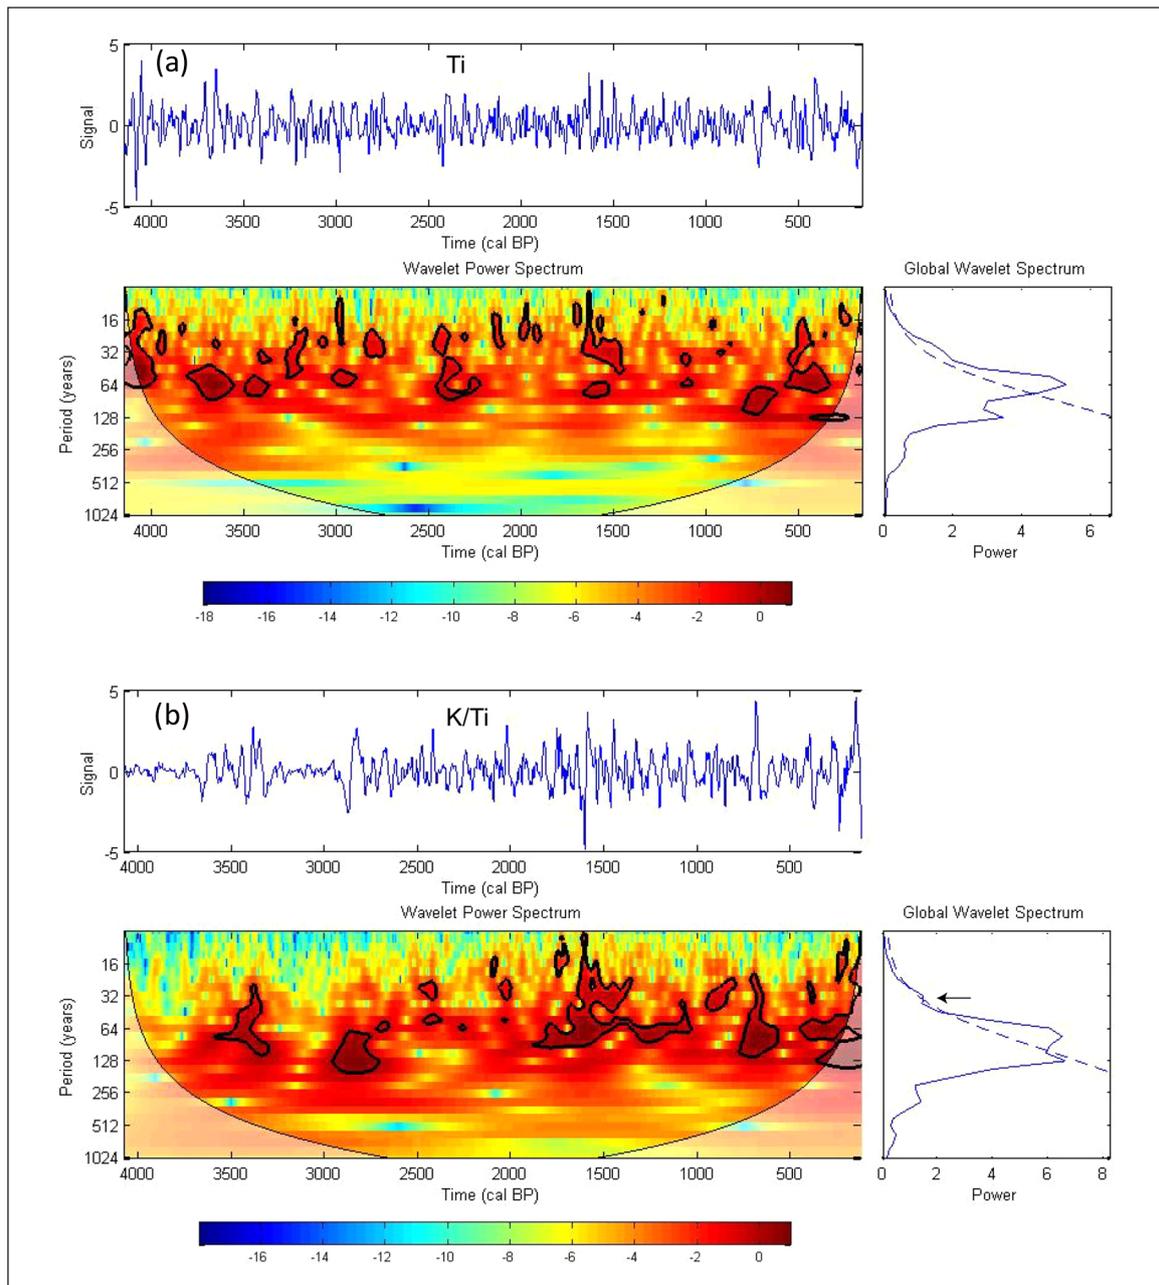

### North Atlantic oceanic forcing

On longer timescales, clastic supply fluctuations depict significant periodicities centered at 550–600 years since the last significant St. Sorlin glacier advance c. 2800 cal. BP (e.g. Chapron et al., 2008) (Figure 6). This low-frequency fluctuation was associated with changes in North Atlantic deep water (NADW) circulation (Chapman and Shackleton, 2000) which are also coherent with fluctuations in atmospheric conditions over Greenland (Stuiver et al., 1995). Our results thus imply significant impact of late-Holocene climate variability over the North Atlantic region on alpine climate and glacier mass balance at the centennial timescale.

Furthermore, clastic fluctuations depict significant pluridecadal periodicities centered at 30 years and especially at 60–70 years (Figure 7). These pluridecadal oscillations were observed throughout the sequence within Ti fluctuations, while they were not recorded during the two warmer periods occurring during the Bronze Age within K/Ti (and K) fluctuations. They are consistent

with typical periods of the NAO (Appenzeller et al., 1998; Cook et al., 1998; Hurrell and van Loon, 1997; Luterbacher et al., 1999) and in North Atlantic climate variability (Schlesinger and Ramanakutty, 1994). We suggest that darker laminations observed throughout the record (Figure 2) are associated with extreme and/or long NAO+ phases possibly forced by SST pluridecadal variability in the North Atlantic Ocean and result from associated warmer and drier conditions. Similarly, both organic intervals deposited during the Bronze Age may reflect prolonged NAO+ periods.

On decadal and longer timescales, the variation in the NAO could be forced by the North Atlantic SST variability (Kushnir, 1994; Rodwell et al., 1999) and there could possibly be a coherent but sporadic relationship between the amplitude and phase of the NAO and the SST (Higuchi et al., 1999). According to these authors, the amplitude and phase of the interdecadal component of the NAO are modulated by the North Atlantic SST at cycles of 30 and 60 years, respectively. The NAO may also influence the

**Figure 7.** Pluridecadal variability of Ti (a) and K/Ti (b) over the last 4100 years obtained by removing the long-term variations from the annual time series as in Chapron et al. (2002). Sampling period: 4 years. The lighter area denotes the COI and black contours represent the 95% confidence level based on a red-noise background (colour figure available online).

intensity variability of deep convection and thus of the meridional overturning circulation (MOC) (Curry et al., 1998; Dickson et al., 1996), which also exhibits variability at periods near 30 and 60 years in a coupled atmosphere/ocean general circulation model (Zhu and Jungklaus, 2008).

On the other hand, Schlesinger and Ramankutty (1994) identified in the global climate system a temperature oscillation of 65–70 years attributed to an internal oscillation of the ocean/atmosphere system. Furthermore, Knudsen et al. (2011) showed that a persistent 55–70 years oscillation characterized the North Atlantic Ocean–atmosphere variability over the last 8000 years. The roughly 65-year oscillation of North Atlantic SSTs (Atlantic Multidecadal Oscillation, AMO; Kerr, 2000) is assumed to be related to multidecadal fluctuations of the thermohaline circulation (Delworth and Mann, 2000; Knight et al., 2005). This persistent natural oscillatory mode has been recognized to affect climate on surrounding continents because of changes in the

intensity and direction of propagation of cyclones and anticyclones (e.g. Knight et al., 2006). In Europe, positive AMO is associated with positive near-surface air temperature anomalies. In addition, glacier mass balance in Switzerland has been recently significantly anticorrelated to the Atlantic Multidecadal Oscillation (AMO) index (Huss et al., 2010). This is consistent with the decadal fluctuations of the North Atlantic climate influencing European surface-temperature, precipitation and storminess through evaporation, precipitation and atmospheric-heating processes (Keenlyside et al., 2008; Rodwell et al., 1999). Furthermore, Sutton and Hodson (2005) provided evidence that ‘basin-scale changes in the Atlantic Ocean, probably related to the thermohaline circulation, have been an important driver of multidecadal variations in the summertime climate of western Europe’. The oscillations of clastic supply recorded in proglacial Lake Bramant thus likely indicate that North Atlantic oceanic variability may influence glacier mass balance present in

the watershed and regional climate through coupling with the atmosphere at various timescales.

## Conclusions

The geographic location and the high altitude of the Grandes Rousses glaciers in the Western French Alps may explain their relatively high sensibility to the west-component atmospheric fluxes originating from the Atlantic Ocean, i.e. to depression regimes directly reflected by the NAO index. The glacial advances in the massif occurred generally slightly earlier than the much larger Swiss alpine glaciers, probably because of their small size which makes them more sensitive to climatic fluctuations. Clastic fluctuations exhibit enhanced pluridecadal periodicities that appear to be related to similar NAO variations. A NAO-like period in our data would be a consequence of variations in rainfall and snow accumulation during late autumn and winter over the watershed of proglacial Lake Bramant, which would partly influence glacier mass balance. The cycle centered at 60–70 years could also be related to internal variability between the North Atlantic Ocean/atmosphere, possibly reflecting the Atlantic Multidecadal Oscillation. In addition, longer periods (550–600 years) observed in clastic fluctuations since 2800 cal. BP strongly suggest that other large-scale climatic phenomena such as variations in NADW production is leading to changes in temperature, precipitation and storminess in the alpine massif. The North Atlantic Ocean and climate variability seem therefore to play a major role on these high altitude alpine climate and glacier mass balance during the late Holocene.

## Acknowledgements

The authors would like to thank Flavio Anselmetti (Bern University, Switzerland) for his contribution during the seismic and short coring survey in 2003 and to Bruno Axelard (Refuge de L'Etendard) for his support during the piston coring operations realized in collaboration with O Lie and the coring team from Bergen University (Norway). Jean-François Cr mer is acknowledged for his helps in the laboratory. We also acknowledge J rg Luterbacher (University of Giessen, Germany), Elena Xoplaki (Bern University) and Neil Roberts (Plymouth University, UK) for providing Figure 1(a). Thanks are also due to David Fortin (INRS-ETE, Canada) for discussions and to Pierre Francus (INRS-ETE) and Flavio Anselmetti (Bern University) for their detailed comments on an earlier draft of the manuscript. We also acknowledge Atle Nesje (Bergen University) for his editorial guidance and two anonymous reviewers for their constructive comments.

## Funding

This study was supported by the French Mountain Institute, the Natural Sciences and Engineering Research Council of Canada (NSERC) and by the Canadian Foundation for Innovation (CFI).
