Zinc-rich clays in supergene non-sulfide zinc deposits. 1 "Fertilization" of barren clays in supergene non-sulphide zinc deposits 2 3 Choulet F.<sup>1,\*</sup>, Buatier M.<sup>2</sup>, Barbanson L.<sup>2</sup>, Guégan R.<sup>2</sup>, Ennaciri A.<sup>3</sup> 4 5 <sup>1</sup>: Chrono-Environnement, Université de Franche-Comté/CNRS (UMR6249), Besançon, France 6 <sup>2</sup>: ISTO, Université d'Orléans/CNRS (UMR7327), Orléans, France 7 <sup>3</sup>: Groupe Managem, Casablanca, Morocco 8 \*: corresponding author <u>flavien.choulet@univ-fcomte.fr</u> 9 10 Abstract 11 12 The nature and the origin of zinc clays are poorly understood. Based on the example of the 13 Bou Arhous Zn-Pb ore deposit in the Moroccan High Atlas, this study presents new advances for the 14 characterization of barren and mineralised clays associated to zinc non-sulphide ores. In the field, white 15 to ochre granular clays are associated with willemite, whilst red smooth clays fill karst-related cavities 16 cutting across the non-sulphide ore bodies. Red clays (kaolinite chlorite, illite and smectite) present 17 evidence of stratification that reflects internal sedimentation processes during karst evolution. White 18 clavs contain 7Å-clay mineral/smectite irregular mixed layers with less than 20% of smectite layers. 19 The willemite crystals are partially dissolved and are surrounded by authigenic zinc clay minerals. 20 WDS analyses on newly formed clay aggregates have revealed that this mixed layered mineral is 21 composed by fraipontite and sauconite. CEC measurements support that zinc is only located within the 22 octahedral sheets. These new results support the following process: 1) dissolution of willemite, leading 23 to releasing Si and Zn, 2) interaction between Zn-Si rich solutions and residual-detrital clays, 3) 24 neogenesis of mixed-layered zinc clay minerals that grow over detrital micas, representing the source 25 for Al. 26 27 Keyword: supergene zinc deposits, karst, clay minerals, Morocco 28 29 1) Introduction

31 Clays are often considered to be a knotty challenge for ore processing (Connelly 2011; Lim 32 **2011**), because of their size and shape characteristics. The typical problems met by the mining industry 33 encompass the difficulties of handling, crushing, screening, milling and classifying clay-rich raw 34 material. High grade of clay results in poor selectivity and thus significantly slow flotation kinetics 35 (e.g. Bayraktar et al. 1998; Fuerstenau et al. 2007). Occurrence of clays in the ore may also affect 36 leaching techniques by increasing pulp viscosity. Despite many efforts to fathom these crucial 37 difficulties, cost of solutions is considerable and hence clays act as a brake on ore extraction and 38 processing. Another difficulty with clays associated to ores is their potential to trap metal (Newman 39 1987). Hence a noteworthy amount of economic elements is captured in clays, which are often difficult 40 to process for recovery (e.g. Ni-rich clays, Crundwell et al. 2011). Understanding the nature and the 41 origin of clays associated to ores is critical for designing flowsheet and identifying potential 42 unconventional sources for critical metal extraction and recovery.

43 Recent development of coupled techniques of leaching, solvent extraction and electrowinning 44 and their application to zinc smelting (Gnoinski 2006; de Wet and Singleton 2008; Abkhoshk et al. 45 2014) have contributed to revive interest in the disregarded non-sulphide deposits with successful 46 application in Namibia, Peru and Morocco. Supergene non-sulphide zinc deposits are formed during 47 weathering in relation with tectonics and climate (Hitzman et al. 2003). Such deposits are described 48 around the world and occur in various geological environments, from silicoclastic to carbonate host 49 rocks (Boni and Large 2003). Based on genetic processes at their origin, three types of supergene 50 deposits have been distinguished: 1) direct-replacement deposits, 2) wall-rock deposits and 3) karst-51 filling deposits (Hitzman et al. 2003). These different processes may occur together in a given deposit, 52 affecting the texture of ores and providing an intricate mineralogical record. This includes carbonates 53 (smithsonite), hydrated carbonates (hydrozincite), silicates (willemite), hydrated silicates 54 (hemimorphite) and various rare minerals, including clays such as sauconite, a smectite containing up 55 to 50 % wt of ZnO (Ross 1946) or more rarely fraipontite, a zinc bertherine (Fransolet and 56 Bourguignon 1975).

In many supergene zinc deposits, mineralised clay material represents a significant economic resource that cannot be ignored (e.g. up to 30 % of the ore at Accha in Peru, **Boni et al. 2009a**). The occurrence of such amount of clays in the ore requires desliming and results in lower zinc recovery (**de Wet and Singleton 2008**), although the impact of clays is probably lower than expected from 61 mineralurgical tests (Boni et al. 2009b). Besides, the ability of clays to sorb or catch Zn<sup>2+</sup> cations 62 located within the interlayer space of swelling clays is well known (Bradbury and Baeyens 1999; 63 Churakov and Dähn 2012), implying natural clays may represent an economic potential of zinc 64 recovery without much efforts. Although zinc enriched clays are frequently described in supergene 65 deposits, clear identification of the nature of clay minerals remains rare and the classical sauconite 66 assessment is highly speculative. In addition, the origin of zinc clays and its place within the ore 67 evolution remain badly understood.

68 This study investigates the characterisation of zinc clays of the Bou Arhous deposit in the 69 Moroccan High Atlas. This deposit is hosted in Lower Jurassic limestone, and ore is mainly willemite, 70 whose origin is not clearly understood (Choulet et al. 2014). Willemite is associated to various types 71 of clayey material, presenting differences in mineralogy, texture and Zn content. The Bou Arhous ore 72 deposit represents a key natural example to understand the origin of zinc-bearing clays and their place 73 in the ore deposition. Using microscopic observations and classical techniques for investigating clay 74 minerals, we aim at characterizing the nature of clays recorded at Bou Arhous and debate on their 75 origin. Further quantification of the cation exchange capacity (CEC) allows us to discuss the potential 76 of zinc recovery.

77

#### 78 2) Geological setting of the Bou Arhous ore deposit

79

The Bou Arhous Pb-Zn ore deposit (32.27°N, 3.76°W) is located in the Moroccan High Atlas
range, 60 km to the north-east of Errachidia city (Fig. 1A). The local geology of this deposit has been
extensively studied by Leblanc (1968) and recently revisited in Choulet et al. (2014).

The formation of the High Atlas intra-continental fold-and-thrust belt (**Mattauer et al. 1977**) results from the far-field effect of the Alpine collision events since mid-Tertiary (ca. 40 Ma) and up to Pleistocene (**Frizon de Lamotte et al. 2009**). As a consequence, the Mesozoic sedimentary basins formed during the opening of Tethys and Atlantic Oceans have been affected by inversion tectonics accompanied by regional uplift and localized exhumation of Lower Jurassic and Triassic strata in the core of narrow anticlines. Thereafter, exhumed strata experienced surface weathering leading to the karst development in the Jurassic limestone (**Choulet et al. 2014; Charles et al. submitted**).

90 The Jbel Bou Arhous range is one of these ENE-WSW trending faulted anticlines that exhume 91 the Triassic and Lower Jurassic strata (Fig. 1B). The fold-related "Grand Accident" thrust is rooted in 92 the Triassic substratum (Figs. 1B and 1C; Teixell et al. 2003) and represents a reactivated normal fault 93 that delimitated contrasting paleogeographic domains of the former Tethys Sea (Warme 1998). To the 94 north of the fault, deep-seated dolomitic limestone is almost barren, whereas massive limestone of the 95 southern domain originally deposited in reef or para-reef environments includes lenses of base metal 96 sulphides (Figs. 1B and 1C). At site of the Bou-Arhous mine located in the footwall of the "Grand 97 Accident" thrust, the two limbs of the anticline are vertical (Fig. 2A) or slightly recumbent and the fold 98 hinge is missing (Fig. 1C). Host rocks of mineralisation include Sinemurian black limestone, locally 99 interbedded with thin layers of greyish marls (Fig. 2B), which have experienced slight dolomitisation 100 during diagenesis and emplacement of base metals sulphide lenses (Leblanc 1968). In depth, 101 mineralisation is tectonically juxtaposed along the "Grand Accident" thrust to the Triassic variegated 102 shales associated to gypsum (Fig. 2C).

103 Following exploration campaigns in the 1960's, the Bou Arhous mine has been exploited by 104 Managem since the early 2000's and reserves have been estimated at 250 kt grading 4 % Pb and 16 % 105 Zn. Mineralisation consists of an intricate network of various-sized veins, extending over 18000 square 106 metres. Veins up to 10 metres in width parallel the stratification and dip steeply to the north (Fig. 2A). 107 Non-sulphide zinc-bearing minerals include willemite, hydrozincite, hemimorphite and smithsonite. 108 Gangue minerals include automorphous white carbonates, such as calcite and dolomite (Fig. 2D), 109 emplaced during the early sulphide stage (Choulet et al. 2014). Willemite is finely associated to galena 110 remnant and cerussite, forming a well-defined black ore. Black ore generally occurs as disseminated 111 patches enclosed in very fine-grained clay-rich material (Fig. 2E), showing a variety of colours. Hence, 112 different types of clayey material have been distinguished and they are detailed in the following 113 section.

114

#### 115 3) The different types of clay deposits at Bou Arhous

116

Previous investigation of the clayey material associated to the mineralisation (Leblanc 1968) suggested the existence of two types of clays. Reddish and smooth clays occur as infilling material of the karstic cavities and were considered of detrital origin as evidenced by the layering structures. These 120 clays are barren, but they locally contain some fragments of the non-sulphide mineralisation. In
121 contrast, white and granular clays are frequently associated to willemite and Leblanc (1968) suggested
122 that these clays might correspond to newly formed clay minerals with up to 23 % of Zn (Gaudefroy
123 1953).

Based on a recent detailed field study, a new examination of the clay materials has been carried out and we now distinguish three types of clayey material, which may coexist in a same area (Fig. 3A).

127 1) Red clayey material fills a network of connected cavities, sinkholes and tunnels, related to the karst 128 of Bou Arhous (Fig. 3B). A sub-horizontal bedding (Fig. 3C) with evidence of grain size sorting is 129 frequently observed, as well as various-sized clastic fragments of ore and host limestone. The aspect of 130 the red clayey material may be locally smooth, but is often silty or sandy due to millimetre-sized quartz 131 grains. This red clayey material corresponds to the reddish and smooth clays described by Leblanc 132 (1968).

2) White clayey material occurs as a fine-grained matrix embedding disseminated patches of willemite associated with carbonates and galena. It forms either a thin and partial rim between the black ore and the red clays (**Fig. 3D**), or a widespread impregnation in the mineralisation (**Fig. 3E**). The white colour is not systematic and tends be locally yellowish, indicating a progressive transition to ochre clays. This type partly encompasses the white granular type observed by Leblanc (**1968**).

3) A third type, namely ochre clays has been found as cavity-infilling material (Fig. 3F) or as a mixture
of white and red clayey materials (Fig. 3A). Ochre clays share similar features with white clays, such
as their association with black ore but this latter one is less preserved than in the case of white clays.
Ochre clays may also occur as isolated material without any spatial connection with white and red
clays.

143

144 4) Sampling and methodology

145

146 *4.1) Bulk chemical composition* 

147

Fifty-eight rock samples have been collected at Bou Arhous mine and include host-rocks(Triassic shale and Jurassic limestone and marl) and the three types of clayey material (red clays, white

150 clays and ochre clays), listed in Table 1. Among them, thirty-four samples have been duplicated for 151 analysing the chemical composition. The chemical composition measurements using acid digestion 152 procedure have been carried out in Managem Group lab, at Marrakech, Morocco. For major elements, 153 0.5 g of a crushed sample (< 200  $\mu$ m) has been dried and dissolved by fusion at 500°C during 45 154 minutes with 2.5 g of sodium peroxide in a zirconium crucible. The residue was then dissolved in HCl 155 and the solution has been analysed by ICP-AES ULTIMA 2C. For minor elements, a 0.25 g split has 156 been heated (220 °C during 45 minutes) in HCl (50%) – HNO<sub>3</sub> (50%) to fuming and the solution was 157 analysed by ICP-MS Thermo X'Serie 2.

158

159 4.2) Clay fraction study

160

161 In addition, for twenty-two samples, the clay fraction (<2  $\mu$ m) has been separated by 162 decantation using the following procedure. A rock sample has been crushed using a Retsch PM200 ball 163 mill and manually ground in agate mortar. The rock powder has been dissolved in distilled water and 164 dispersed with a magnetic stirrer. Progressive addition of HCl (0.2M) monitored by continuous pH 165 measurements was used to remove carbonate at room temperature. Then, the solution has been washed 166 several times, dispersed and placed in a jar for decantation. After about 4 hours, the first five 167 centimetres of the solution containing the clay suspension ( $<2 \mu m$ ) have been withdrawn using a 168 syringe. After removing the supernatant by centrifugation, the residue has been dried and used for 169 further X-ray diffraction (XRD) and cation-exchange capacity measurements.

170 XRD patterns of the whole rock samples and clay fractions have been obtained using a D8 171 Advance Brucker diffractometer equipped with a LinxEye detector, hosted at Utinam lab, Besancon, 172 France. Parallel beam geometry and CuKa radiation at 1.54184 Å has been used. For whole rock 173 sample, the powder was placed in the specimen holder. Acquisition conditions (divergent slit) included 174 a step-scan of 0.5  $^{\circ}$  in the 2-52  $^{\circ}$  interval, with a step time of 0.05 s. For the clay fraction, the powder 175 has been diluted in distilled water and a drop of the solution has been deposited on a glass lamella for 176 dewatering under air-dried conditions. The orientated-aggregate mount (along c axis) was then placed 177 in holder and a step-scan of 0.02  $^{\circ}$  in the 2-30  $^{\circ}$  interval, with a step time of 0.5 s has been used for 178 XRD measurements. A duplicate of the orientated-aggregate mount has been treated for ethylene 179 glycol (EG) saturation, by placing the lamella in a pressurised desiccator overnight. For several

180 samples, a second duplicate has been heated at 550 °C during one hour in a furnace before XRD 181 measurements. EVA software package has been used for data processing and phase identification. The 182 position of 060 reflexion has been determined on clay fraction powders at Institut des Sciences de la 183 Terre d'Orléans, Orléans, France, using an ARL X'TRA diffractometer equipped with Cu anode and a 184 Si solid detector operating at 40 kV and 40 mA. Experimental measurements were carried out at room 185 temperature, with 10 s counting time per 0.02 ° step.

186 Cation-exchange capacity (CEC) measurements have been carried out at the Institut des 187 Sciences de la Terre d'Orléans, Orléans, France following the procedures described in Meier and Kahr 188 (1999) and Ammann et al. (2005). A solution of 0.01M Cu(II)-trien sulphate has been prepared from 189 1.596 g of copper sulphate and 1.508 g of triethylenetetramine. 100+/- 25 mg of clay sample were 190 added to 25 mL of distilled water and to 8 mL of Cu(II)-trien sulphate. The solution has been dispersed 191 using tube roller overnight and was further centrifuged (10 minutes at 6000 rpm) to removed 3 mL of 192 the supernatant. Measurement of  $[Cu^{2+}]$  was performed using Atomic Absorption Spectroscopy (AAS) 193 with 2-8100 Polarized Zeeman Hitachi instrumentation and colorimetric techniques. The CEC was then 194 calculated with reference to the dry clay weight, to the water content and to the amount of captured 195 Cu<sup>2+</sup> ions deduced from AAS measurements. A similar procedure is used for calculating the Zn content in the CEC. Standardisation curves of absorbance for  $[Cu^{2+}]$  and  $[Zn^{2+}]$  gave coefficients of 196 197 determination of 0.999 and 0.987, respectively.

198

#### 199 *4.3) Textural and mineralogical observations*

200

Textural and mineralogical observations have been carried out using optical microscopy (OM) and FEI Quanta 450 Scanning Electron Microscope (SEM) hosted at Femto-ST lab, Besançon, France. The images have been acquired in low vacuum mode (0.7-0.8 mbar) on polished thin sections, with acceleration voltage at 15 kV. An Energy-Dispersive X-Ray Spectrometer (EDS) was coupled to the SEM system providing qualitative determination of the mineral composition using Edax Genesis software package.

207

208 *4.4) Chemical composition of clay minerals* 

210	We have performed quantitative analyses using Cameca SX100 electron microprobe (EPMA),
211	equipped with five Wave-Dispersive X-Ray Spectrometers (WDS) and hosted at Géosciences
212	Montpellier, Montpellier, France. On carbon-coated polished thin-section, we have operated at 20 kV
213	with a beam current at 10 nA. The spot resolution was few micrometres. Quantification of the Na
214	content was not possible due to the interference of the Zn L $\beta$ 1 emission line that fall close to the Na K $\alpha$
215	emission line.
216	
217	4) Results
218	
219	4.1) Whole rock geochemical and mineralogical composition
220	
221	4.1.1) Host rocks
222	The Triassic shales are composed of a mixture of quartz, clay minerals, hematite, goethite, and
223	carbonates including both calcite and dolomite (Table 1). Gypsum is also present in some samples. The
224	major elements content strongly varies due to a variable proportion of carbonates and iron oxi-
225	hydroxides. Variable enrichment in Zn, Pb, Cu and As can be noticed suggesting the local occurrence
226	of sphalerite, galena, and/or other minor metal-bearing minerals.
227	Jurassic rocks including marl and limestone contain clay minerals, calcite, dolomite and
228	quartz (Table 1). Goethite is common. The $SiO_2$ and CaO contents are variable and probably mirror the
229	variable abundance in quartz and carbonate in the samples. Minor elements (Zn, Pb, Cu and As)
230	content remains low except for one sample that contains galena, sphalerite and their respective
231	alteration products.
232	
233	4.1.2) Clayey material
234	The mineralogy of the red clayey material is characterized by a mixture of quartz, clay
235	minerals, calcite with goethite and rare dolomite (Table 1). Despite important variations of CaO and
236	SiO <sub>2</sub> related to carbonate enrichment of some samples (e.g. BA101), the major elements content

content except for Pb and Zn, which display highly variable amounts (e.g. between 830 ppm and 47300

remains constant. The red clay samples do not display any significant variations of the minor elements

ppm for Zn); this could be related to the occurrence of willemite and cerussite impurities in thesesamples.

The white clayey material is composed of a mixture of willemite, galena, quartz, clay minerals and carbonate (dolomite, calcite, and cerussite). Dolomite is almost always observed in white clays, marking a noteworthy difference with red clayey material. The MgO content can therefore reach up to 10 % wt (**Table 1**). The occurrence of Zn and Pb ore in white clays is responsible for high Zn and Pb grade (up to 320000 ppm for Zn and 37100 ppm for Pb).

- In ochre clayey material, clay minerals, quartz, calcite and dolomite are always present, with a common occurrence of cerussite. Chemical compositions of the ochre and white clayey materials are relatively close; indeed they have similar MgO and CaO contents (**Table 1**). Despite the absence of Znbearing phases (sulphide or carbonate) detected from whole-rock XRD analysis, the Zn content varies between 6275 ppm and 237000 ppm.
- 251

The extreme variations of the Zn content in the three types of clayey material cannot be correlated straightforwardly to the mineralogical composition deduced from whole rock XRD measurement, it may be partly due to the presence of willemite impurities, but, for several samples (ochre clays), Zn-bearing clays must be involved to explain tremendous Zn contents, requiring a specific study of the clay fraction.

257

258 4.2) Mineralogical characterisation of the clay fraction

259

260 *4.2.1)* Red clays

261 XRD patterns obtained on the clay fraction of the red clays show a non-expandable phase 262 around 7.1 Å (Fig. 4A), which mainly corresponds to the 001 reflexion of kaolinite as this Bragg peak 263 disappears after heating to 550 °C. Chlorite is significantly present in the mixture as evidenced by the 264 003 peak at 4.74 Å, and the slight offset of 004 reflection (3.55 Å) relative to the 002 peak of kaolinite 265 (3.58 Å). The non-expendable peak at 10 Å may suggest the presence of illite, whereas the 14.6 Å peak 266 that expands to 16.8 Å for EG-treated preparations corresponds to swelling smectite. The broad shape 267 in the domain between smectite and illite 001 reflections suggests the presence of interstratified 268 illite/smectite. By focusing on the position of the 060 reflection (Fig. 4B), a main broad peak at 1.491.50 Å is consistent with the predominance of dioctahedral species like kaolinite and illite, whilst the
secondary peak at 1.541-1.543 Å corresponds to a trioctahedral type like chlorite. Quartz and goethite
are also present.

272

273 *4.2.2) White clays* 

274 XRD patterns of white clays display two identified Bragg peaks at 7.25 Å and 3.61 Å that 275 expand to 7.39 Å and 3.53 Å, respectively, for samples treated with EG (Fig. 5A). This indicates the 276 presence of randomly interstratified smectite and of another clay mineral, characterized at 7 Å such as 277 kaolinite or serpentine. This mixed-layered (ML) clay mineral, dominated by the 7 Å phase, coexists 278 with illite and occasional chlorite. Smectite was detected in samples BA130F and BA134F. Associated 279 phases such as cerussite, willemite, goethite and goethite commonly occur. Whilst the broad peak 280 around 1.50 Å, typical of dioctahedral clays corresponds to the position of 060 reflexion of illite, the 281 thin well-defined peak at 1.54 Å suggests a significant proportion of trioctahedral type clay minerals 282 (Fig. 5B). Although this may be confused with the 1.541 Å peak due to the 211 reflection of quartz, the 283 060 reflexion patterns are similar between samples which may (e.g. sample BA130F) or may not (e.g. 284 sample BA124F) contain quartz (Fig. 5A). For sample BA124, the offset of the broad peak to 1.51 Å is 285 probably an artefact due to a parasite reflexion of zinc silicate (e.g.  $11\overline{6}$  for willemite or 530 for 286 hemimorphite).

287

288 *4.2.3*) Ochre clays

XRD patterns of the ochre clays do not strongly differ to those of the white clays, with the presence of randomly interstratified smectite and 7 Å mineral (**Fig. 6A**). But the shift of this Bragg peak to lower angular value after EG treatment (up to 7.72 Å and 3.45 Å) suggests a higher smectite proportion in the ML. In addition, illite and smectite are also displayed, as well as cerussite and goethite. The predominance of the trioctahedral type over the dioctahedral type is obviously shown on the 060 reflexion pattern (**Fig. 6B**), with a well-defined thin peak around 1.542 Å and a broad and unclear peak around 1.51 Å, probably polluted by the reflection of minor zinc minerals.

296

297 *4.3)* Cation-exchange capacity (CEC) of the different types of clays

299 Although previous observations obtained through XRD measurements have stressed out a 300 possible trend between the type of clays and the amount of Zn content, it does not provide any 301 information on the localization of Zn within the phyllosilicate structure (i.e. in the interlayer space as 302 an exchangeable cations or included in the phyllosilicate sheets). The CEC measurements represent an 303 easy and convenient method allowing one to determine the proportion of exchangeable zinc in the three 304 kinds of clay samples (Table 2). The CEC value of the red clays is between 30 and 38 meq/100g, 305 consistent with a mixture of illite, kaolinite and smectite. For 3 out of 4 samples, the amount of 306 exchangeable Zn represents less than 1% of the CEC and is therefore not significant. In contrast, for 307 sample BA121, which may be considered as an exception, more than 40% of the CEC contains 308 exchangeable Zn; this may partly explain the high Zn content (30000 ppm) of this sample, but this 309 assumption is not valid for other mineralized samples such as BA127 (Table 1). For the white clays, 310 the CEC values are bracketed between 9 and 27 meq/100g; it may be related to the high content of ML 311 dominated by a non-swelling 7 Å mineral, with a typical CEC value of 5 to 15 meq/100g (Ma and 312 Eggleton 1999). In the ochre clays, the CEC values may reach 41 meq/100g, as the smectite proportion 313 in the ML is probably higher than in the white clays (Fig. 6A). The amount of exchangeable zinc in the 314 CEC is very low for both white and ochre clays, suggesting that zinc is mainly included within the 315 octahedral sites of the clay mineral structure.

316

#### 317 *4.4) Textural observations (OM and SEM)*

318

319 SEM observations of the red clays confirm the presence of a mixture of clay minerals, with 320 dense aggregates of clay platelets (Fig. 4C). EDS analyses show that clay minerals are composed of Si, 321 Al, and K, in accordance with the occurrence of illite/kaolinite mixture as identified on XRD patterns 322 (Fig. 4A). Isolated laths or sub-euhedral lamella of chlorite are associated to K-rich clays and quartz 323 sub-rounded clasts too (Fig. 4C). The bulk clayey matrix displays lighter and porous aggregates of 324 lamella-shaped minerals (Fig. 4D); EDS analyses of these patches show Zn enrichment and a low K 325 content relative to the mixture of kaolinite and illite. Descloizite, a zinc vanadate that precipitates under 326 high oxidizing weathering conditions has been locally found (Fig. 4E) and may explain, together with 327 the zinc clays, the anomalous high Zn content of some red clayey material samples (e.g. BA121 and

BA127; Table 1). It is worth to notice that no particular phase corresponding to zinc clays was detectedby XRD analyses suggesting a low abundance of these zinc-bearing minerals.

330 Optical microscope observations of the white clays show that clay minerals occur in cavity 331 within the ore formed by roundish aggregates of willemite and disseminated galena coated by cerussite 332 (Fig. 5C). SEM imaging of the clayey material in these cavities reveals a roughly honeycomb texture 333 of the newly formed clay minerals (Fig. 5D). Locally, the micrometre-sized clay sheets are densely 334 aggregated and form patches disseminated in the cavity. EDS analyses reveal that these clays are rich 335 in Zn and poor in K, but sometimes K-rich fragments are found, suggesting an intricate association of 336 both clay types. In most cases, the electronic contrasts between dark K-rich clays and light Zn-rich 337 clays are so clear that it is easy to separate to the related domains, which present a very different 338 textural arrangement (Fig. 5E). In the K-rich zone, the illite lamellae coexist with sub-euhedral clasts 339 of quartz. Thin to large bands of Zn-rich clays exposing a honeycomb texture pervade in the cavity and 340 connect to the willemite crystals.

Comparable observations can be made in the ochre clayey material, which exposes cavities filled by clay minerals within a primary association of willemite, dolomite and cerussite (**Fig. 6C**). A honeycomb texture of Zn-rich clays analysed by EDS is frequently observed (**Fig. 6D**). In the weakly dense aggregates, the micrometre-sized clay crystals can be individualised, exposing a typical sheeted aspect. Relics of illite lamellae and clasts made of quartz are found isolated in the Zn-rich clay matrix (**Fig. 6E**).

347 The clay minerals and especially the zinc-bearing type are closely associated to willemite; 348 euhedral willemite crystals present evidence of partial dissolution that preferably affects edges or sites 349 of crystalline defect (Fig. 7A). Zinc clays may precipitate in this newly formed porosity (Fig. 7B), but 350 are mainly found as flakes or platelets either within the K-rich clayey material composed by illite, 351 kaolinite and chlorite (Fig. 7C) or along cleavage cracks to form mineralized ribbons (Fig. 7D) that 352 fossilized the paths of reactive waters. The honeycomb texture of newly formed zinc clays is frequent 353 in the core of the domain, whereas the clay sheets appear squeezed at the interface with willemite 354 (Figs. 5E and 7E). Together with the euhedral shape of the willemite crystal and the evidence of 355 successive rims of willemite, this supports the crystallization of a second generation of willemite 356 (willemite II in Fig. 7F) after the formation of the Zn-rich clays.

359

360 WDS quantitative measurements have been carried out on clay aggregates from white and 361 ochre types (samples BA02, BA05 and BA05) and the results are reported in Table 3. Only data with a 362 total over 80 %wt, consistent with the range of expected zinc clays minerals (fraipontite, sauconite) 363 have been retained for discussion. The ZnO content, between 1.86 % and 49.39 % appears negatively 364 correlated to the K<sub>2</sub>O content varying from 10.01 % to 0.05 %. Similarly, the SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> contents 365 decrease with K<sub>2</sub>O. Ca, Fe, Mg and Pb cations are present in minor amount and we observe show slight 366 variations without any relationships with other major elements. Several groups depending on their ZnO 367 and K<sub>2</sub>O content and their total oxide content have been distinguished (Table 3).

368 For K-rich clayey material, structural formulae were calculated for 22 negative charges (Table 369 3). For analyses 10, 57 and 58, the number of octahedral cations is around 2 and the number of 370 interlayered cations reaches 0.8, consistent with the occurrence of illite. Analyses 19, 20, 29 and 38 371 show a significant K<sub>2</sub>O content (around 2 %) and Zn enrichment up to 30 %; they present a total of 372 analysed oxides around 84 % consistent with pure Zn smectite, i.e. sauconite (Table 3). For seven 373 individuals analyses that present a total of analysed oxides around 93 % and a K<sub>2</sub>O content between 0.2 374 % and 0.6 %, structural formulae were calculated for 22 negative charges assuming a T-O clay mineral 375 structure. The number of cations in octahedral sites is around 5.5 attesting that the analysed particles 376 are trioctahedral Zn-rich T-O minerals such as fraipontite. The value of  $M^+$  ( $M^+$ =K+2Ca) is 377 significantly high, and may mirror surface adsorption of alkaline cations. The 17 remaining analyses 378 display a total oxide between 84 % and 93 % and/or a variable content in K<sub>2</sub>O; they probably 379 correspond to a mixture of the above-mentioned end-member clay minerals. The structural formulae 380 calculations were based on 22 negative charges. One can notice the number of cations in the octahedral 381 sites (3.4-3.5) largely exceed the ideal value of 3 (Table 3).

382

383 5) Discussion

384

385 *5.1*) Identification of the nature of Zn clays

387 The results obtained from microscopic observation and XRD analysis, suggest the presence of 388 Zn-bearing clays in the three types of clayey material at Bou Arhous mine, especially in the white and 389 ochre types. By comparing the results given by the two methods, we can deduce that the zinc-rich 390 sheeted aggregates disseminated in the samples correspond to a 7 Å mineral locally interstratified with 391 smectite sheets. In the literature, several types of zinc clays have been described. Sauconite, a 392 trioctahedral smectite close to saponite is the most described clay type and was reported in several 393 deposits in Northern America (Ross 1946), Peru (Boni et al. 2009a), Southern Africa (Kärner 2006; 394 Terraciano 2008; Boni et al. 2011) and Iran (Daliran et al. 2009). Fraipontite (also known as 395 zinalcite), a zincian berthierine (7 Å mineral) has been found in supergene zinc deposits in Belgium 396 (Fransolet and Bourguignon 1975), Iberia (Calvo et al. 2007; Will et al. 2014), Italy (Merlino and 397 Orlandi 2001) and Kazakhstan (Chukhrov 1968). Other rare zinc clays are Zn-rich beidellite 398 (Mondillo et al. 2014), baileychlore, a zinc chlorite (Rule and Radke 1988) and hendricksite, a zinc 399 mica (Frondel and Ito 1966; Robert and Gaspérin 1985), the latter two occurring in hypogene 400 environments. Besides, moresnetite (Ross 1946) and vanuxemite (Frondel 1972) have been described 401 as a mixture of zinciferous clays and hemimorphite. No zinc-bearing mixed-layered (ML) minerals 402 have been described, except for illite-zincian smectite ML in Peru (Mondillo et al. 2014).

403 In this study, the WDS compositions of the clay crystals show a negative correlation between 404 K (as well as Al and Si) and Zn, suggesting phase mixing at site of analysis (Table 3). This is in 405 agreement with the microscopic observation that supports an intricate association between the K-rich and the Zn-rich clays. In the  $M^+$  - 4Si -  $3R^{2+}$  ternary plot, classically used for distinguishing the 406 407 dioctahedral and the trioctahedral types (Meunier 2005), our data are scattered along a mixing line that 408 joins the mica pole and the most frequent Zn-clays, namely sauconite and fraipontite (Fig. 8). The data 409 corresponding to the purest Zn-clays do not fall into fields of natural sauconite or fraipontite collected 410 in Peru (Boni et al. 2009a; 2009b), in Namibia (Kärner et al. 2006), in the USA (Ross 1946), in UK 411 (Young et al. 1992) and in Belgium (Fransolet and Bourguignon 1975); data rather fall into an 412 intermediate domain between the theoretical compositions of sauconite and fraipontite. Together with 413 the difficulty of calculating pure sauconite or fraipontite structural formula from our analyses (Table 414 3), this indicates that our zinc clayey material is dominantly a mixture of fraipontite and sauconite, in 415 agreement with the occurrence of interstratified smectite and 7 Å mineral.

416 Numerical modelling of XRD patterns using the Newmod © program (Reynolds 1985) have 417 been carried out to determine the relative proportions of fraipontite and sauconite in the ML mineral. 418 Assuming 1) a mixture of a two-water-layer tri-smectite and a 7 Å mineral, 2) the 00l reflexions given 419 by Faust (1951) and Fransolet and Bourguignon (1975), and 3) a Reichweite value of 0, we have 420 produced the XRD patterns presented in Figure 9. In this calculation, we have neglected the minor 421 effects of  $Zn^{2+}$  on the geometry of ML structure and therefore on the theoretical positions of 001 422 reflexions. The best simulation to describe the measured XRD pattern is obtained for a mixture 423 containing 80% of fraipontite and 20% of sauconite, namely R0 fraipontite (0.8)/sauconite (Fig. 9). To 424 validate this composition, we have recalculated the structural formula assuming a mixing of sauconite 425 and fraipontite at a ratio of 1:4. Based on 39O, the sum of cations in the octahedral sheets is between 426 14.2 and 15 for low K<sub>2</sub>O individual data; this value, slightly lower than the ideal value of 15 for the 427 trioctahedral type corroborates the hypothesis of R0 fraipontite(0.8)/sauconite mixed-layered mineral 428 as the zinc-bearing clay mineral. Although such composition of interstratified mineral has never been 429 reported in the literature, the occurrence of the sauconite-fraipontite association has been described in 430 several natural examples of supergene non-sulphide zinc deposits (Foord et al. 1983; Young et al. 431 1992; Maltsev and Korshunov 1988), or even found in experimental works (Esquivin 1957; 1960).

432

### 433 5.2) Genetic processes accounting for Zn-clays formation

434

Results obtained on whole-rock samples show the difficulty of identifying significant differences
between the three types of clayey material to understand their genetic link with the ore and the host
rock. Despite these difficulties, the following implications may be deduced from the above-mentioned
analysis:

439 - Dolomite is present in the Jurassic limestone and in the gangue of Zn-Pb ore. Its occurrence
440 in the ochre and white clayey materials and its relative absence in the red one may indicate different
441 genetic processes accounting for their respective origin.

442 - Microscope observations have shown that Zn-clays are very frequently associated to detrital
443 illite, which is dominant in the red clayey material. Zinc enrichment of clay minerals in the white and
444 ochre clayey materials is consistent with the neogenesis of mixed layered fraipontite(0.8)/sauconite
445 minerals, requiring sources for zinc, silica and aluminium.

The main zinc-bearing mineral at Bou Arhous is willemite, whose conditions of formation
remain unclear (Choulet et al. 2014). It may have been formed under supergene conditions as
exemplified by the deposits in Nevada (Takahashi 1960), or in Zambia (Terracjano 2008).
Alternatively, a hydrothermal or hypogene origin for willemite (Brugger et al. 2003; Hitzmann et al.
2003, Boni et al. 2011) could be envisaged, but no field and mineralogical observations are currently
supporting this hypothesis.

452 The origin of willemite in such supergene environment is not clearly understood as this 453 mineral is mostly described in hypogene or hydrothermal deposits (Hitzman et al. 2003; Coppola et 454 al. 2008). Its occurrence at Bou Arhous may suggest either a low-temperature hydrothermal stage or 455 exceptional physico-chemical conditions characterised by a combination of high silica activity, low 456 P(CO<sub>2</sub>)<sub>e</sub>, alkaline conditions and oxidizing environment (Choulet et al. 2014). At 25°C, willemite may 457 be partly dissolved by meteoric waters rich in Ca and poor in Si (Brugger et al. 2003); such conditions 458 are reached in karst environment because of water-host rock interaction. This can explain the evidence 459 for supergene dissolution of willemite, releasing Zn and Si in the solution (Figs. 7A and 7B). This 460 dissolution is probably congruent as no quartz or silica gel, incorporating the silicon in excess, remains 461 or precipitates in the secondary porosity. The addition of Zn and Si ions in the solution changes 462 equilibrium and the solubility of the Zn-bearing phases strongly depends on the pH conditions 463 (Takahashi 1960; Brugger et al. 2003). As no smithsonite or hydrozincite precipitation has been 464 observed in our samples despite high P(CO<sub>2</sub>)<sub>g</sub> due to karst buffering, slightly acid (ca. 5) conditions 465 must be envisaged to transport the  $Zn^{2+}$  ions as chlorozinc(II) complexes (**Ruaya and Seward 1986**) 466 and to enable a further precipitation of zinc clays. The absence of widespread hemimorphite is difficult 467 to understand, as this phase is supposed to precipitate under acid pH conditions and relatively high 468 silica activity (Takahashi 1960; McPhail et al. 2003); however, this may be explained by the limited 469 field of hemimorphite stability and its sensibility to strong P(CO<sub>2</sub>)<sub>g</sub> variations (Reichert and Borg 470 2008).

The availability of Al is also critical for the neogenesis of the Zn clays, and requires a local source because of the low mobility of Al in meteoric waters. The Zn clays are often associated to the K-rich clays, mainly illite as evidenced by the XRD patterns of the white and ochre clayey materials. At the scale of the cavity, the pervasion of the Zn-rich clays in the material dominated by the K-rich clays shall suggest a pseudomorphosis of primary illite and smectite and their replacement by the 476 mixed-layered clay minerals (Figs. 5D or 6E). The very close association of illite and Zn clays 477 suggests that partial dissolution of external illite layers, due to hydrolysis and the break up of Al-O and 478 Si-O bonds, contributes to releasing Al and Si, further incorporated in the newly formed ML clay 479 minerals. The Zn clays may also pseudomorph after dissolved willemite (Fig. 7B), but this requires a 480 close source for Al.

481 In karstic environments, the physico-chemical conditions of meteoric waters continuously 482 change due to carbonate buffering. A rapid increase of pH causes tremendous variations of the 483 solubility of zinc silicates like willemite that can further precipitate even at surface temperature and 484 under neutral conditions (Brugger et al. 2003). This precipitation of secondary willemite (Willemite 485 II) forming euhedral rim around primary willemite (willemite I) leads to squeezing of newly formed 486 zinc clays (Fig. 7E and 7F). As a consequence, the honeycomb texture is locally erased, and jamming 487 contributes to emphasize the very fine mixing between illite and ML clay minerals (Fig. 7E). 488 Secondary willemite also occurs as idiomorphic crystals in the open space of the clayey cavities (Fig. 489 7D) or as infilling material within fractures of primary willemite (Fig. 7F).

490

#### 491 5.3) Conditions for Zn mineralisation of clays and relation to the ore evolution

492

The mechanisms of Zn-rich clays formation have been rarely reported in the literature. In Zn ore deposits of Peru, Boni et al. (2009a) have identified sauconite and altered feldspars and they proposed that sauconite in silicoclastic host rocks may result from interaction between feldspar weathering and Zn-rich solution derived from supergene dissolution of zinc sulphide. At Abenab West ore deposit (Namibia), hosted in limestone, a progressive enrichment in Zn and Mg of barren clays is suggested, but details of the nature of zinc clays and the processes related to their neogenesis are presently not available (**Terracjano 2008**).

Like Abenab West ore deposit, zinc ore at Bou Arhous is hosted in limestone that has developed a large karst network since its exhumation at surface (**Leblanc 1968**). The Bou Arhous karst presents some non-dissolved material concentrated in various-sized cavities. Field observations have shown that this red clayey material is composed by a fine succession of silt and clay horizons that present sedimentation features. The red clay type may correspond to "residual" clays, which generally show mixing components between detrital sources and insoluble parts of the dissolved limestone 506 (Chamley 1989). The residual red clays are composed of clay minerals like illite, chlorite, kaolinite 507 and smectite, iron oxi-hydroxide and quartz. This composition is somehow similar to that of the 508 classical peri-Mediterranean karst-related clayey infilling, known as *terra rossa*, that shows stratiform 509 accumulation of red clayey material in cavity formed after limestone dissolution (e.g. **Blanc and** 

510 Chamley 1975; Moresi and Mongelli 1988; Iacoviello and Martini 2013).

- 511 The red clays are originally barren (Table 1), but may be fertilized by several complementary
  512 processes that includes:
- 513

- Sedimentary recycling or zinc ore fragments, such as willemite (**Figs. 3C and 3D**).

- 514 Precipitation of newly formed zinc-bearing minerals like descloizite (Fig. 4E), which is
  515 typical of high oxidising supergene environment (Boni et al. 2007).
- 516 Adsorption of the  $Zn^{2+}$  cations at the clay surface or fixing of the  $Zn^{2+}$  cations in the 517 interlayer, as indicated by the amount of  $[Zn^{2+}]$  released after the CEC measurements (**Table 2**). This 518 process is well known in the literature as many studies have focused on the capacity of clays to trap 519 heavy metals like Zn (e.g. **Bradbury and Baeyens 1999; Dähn et al. 2011**).
- 520 - Precipitation of the Zn-rich clays in small-disseminated patches (Fig. 4D), up to large 521 pervasion (Figs. 5D and 6E) in the red detrital clayey material. This process is able to progressively 522 form the white or the ochre clays found in the Bou Arhous deposit. As seen earlier, this process is 523 characterized by the neogenesis of authigenic clay minerals that nucleate on micas. It may be compared 524 to the epitaxial growth of Zn clays on smectites, which interacts with a solution enriched in Zn and Si 525 (Schlegel et al. 2001; Schlegel and Manceau 2006). These authors reported newly formed clays as a 526 mixture of Zn-saturated TO and TOT trioctahedral phyllosilicates, thereby presenting lot of similarities 527 with the R0 fraipontite(0.8)/sauconite mixed-layered mineral identified in this study. The presence of a 528 clay precursor for nucleation and Al supply is required for the neogenesis of Zn-clays, which also 529 depends on the silica activity (Schlegel et al. 2001). At low Si concentration, Zn may be fixed in 530 polymer chains in structural continuity to the smectite. High Si concentration rather facilitates the 531 neogenesis of authigenic clays and especially the formation of Zn-rich TO phyllosilicates, such as 532 fraipontite. Other experimental studies at supergene conditions have showed that the presence of Al 533 may play a role for the type of clay that precipitates (Tiller and Pickering 1974), with 2:1 layer 534 silicate in Al-free conditions and, in the presence of aluminium, formation of 1:1 layer silicate similar 535 to Zn berthierine, a synthetic product equivalent to fraipontite (Esquevin 1960). Such chemical

controls could be hypothesised to spell out the different types of Zn clays met throughout the world.
The climate dependence classically evoked for the variability of clay types (Chamley 1989) may also
be taken into account, but its role is currently difficult to understand, given the scarcity of reliable data
on Zn clay occurrences.

540 The formation of zinc clays at Bou Arhous is a continuous process during the late supergene 541 evolution of the ore deposit. Initially, zinc was included in sulphide lenses hosted in the Lower Jurassic 542 limestone (Leblanc 1968). The regional uplift and the folding episode related to the Atlas tectonics 543 during the Tertiary have led to an exhumation of the sulphide ore and a verticalisation of the limestone 544 strata (Choulet et al. 2014). As a consequence, the meteoric water has percolated in the fractures and 545 has provoked the dissolution of the limestone and the oxidation of the sulphides. For some unclear 546 reasons, zinc has first re-precipitated as willemite, forming a "black ore" due to its association with 547 preserved galena and cerussite. Willemite has further interacted with karstic waters, probably poor in Si 548 and slightly acid, leading to its partial dissolution and to releasing of Zn and Si in the solution (Fig. 549 10). In parallel, the development of a karst was characterised by the opening of various-sized 550 dissolution cavities filled by detrital supplies and insoluble materials (Fig. 10). At surface conditions, 551 this red clayey material has been pervaded by Zn-Si-rich solutions resulting in the neogenesis of Zn-552 clays (mixed-layered clay minerals) that nucleate on detrital micas. At site of zinc ore concentration, 553 red clays were progressively transformed into white and ocher clays. The further crystallisation of late 554 generations of willemite indicates that this process is continuous in time, highly dependant on the 555 chemistry and dynamics of karstic solutions, and therefore difficult to timely constrain in the ore 556 deposit evolution.

557

#### 558 6) Conclusion

559

This study has revealed the nature of the zinc clays at Bou Arhous deposit and the mechanisms called for their genesis. Although several processes are involved for the metal enrichment of barren clays, the crystallisation of Zn clays appears to be the major one. This neogenesis is related to the interaction between Zn-rich meteoric water and residual clays related to karst evolution. This model has strong implication for the mineral industry, as Zn-rich clayey material grading up to 30% Zn is a non-negligible resource that may be easily identified. The target zones will be the karst cavities located around the original ore body (potentially dissolved); residual clays must fill these cavities, representing the necessary condition for the nucleation of the newly formed clay crystals. The soft nature of the clayey material could probably facilitate mining, at least in case of open-pit extraction, and especially contributes to costs reduction in the early operations.

570 Conversely, by deciphering the mineralogical nature of the Zn-rich clayey material, this study 571 has showed the mixture of authigenic mixed-layered clays and detrital phyllosilicates. Except for rare 572 samples, zinc cannot be recovered easily as it is located within the octahedral sites in each component 573 of the interstratified mineral. Consequently, Zn can only be released by leaching techniques such as 574 solvent extraction, which is relatively efficient for a given clay species like sauconite (Boni et al. 575 **2009b**). But, in the presence of interstratified minerals finely disseminated within detrital barren clays, 576 ore liberation may be more difficult and requires advances for 1) an efficient separation between barren 577 and mineralised clays, and 2) a better selectivity of solvents used. Another consequence of this intricate 578 mineralogical association is the excess of barren materials that need to be handled and processed, 579 thereby representing a major limitation to the economic potential of zinc clays.

580

#### 581 Acknowledgments

582

The authors are indebted to Managem Company for providing access to the Bou Arhous Mine and for having supported bulk rock analyses in their labs. We also thank Goka Katrawi for CEC measurements and Didier Convert-Gaubier for thin-section preparation. This study has benefited from a research grant given by the Région Centre for the 2011-2014 CALAMINES project and from a financial support of Région Franche-Comté with the 2014 "Franco-Suisse" call. Access to SEM facilities of the MIMENTO centre was made in the frame of cooperative projects in the Renatech network.
