Abstract

This contribution presents an original study combining detailed mapping, petrography, whole-rock geochemistry and geochronological constraints on the recently identified LREE (Light Rare Earth Elements) occurrences associated with pegmatitic granite dykes (PGD) from the central Grenville (Lac Okaopéo region). These PGD intrude paragneisses or meta-igneous complexes with a REE mineralization hosted either in monazite-(Ce) or in allanite-(Ce) respectively. The investigated samples display peraluminous signatures and are dominated by a quartz+K-feldspar+plagioclase+biotite+monazite/allanite assemblage. Field relationships and the magmatic textures of the dykes combined with U-Pb dating of magmatic monazite grains at 1005.4±4.4 Ma and 996.7±5.3 Ma (concordant igneous ages) imply that the LREE-rich PGD were emplaced in a post-tectonic setting. Allanite-(Ce) and monazite-(Ce)-bearing PGD have ΣREE contents up to 9242 ppm and 7048 ppm, respectively. The allanite-rich assemblage is consistent with the petrographic assemblage of LREE-enriched PGD identified in the southwestern Grenville Province and elsewhere in the world, but this study constitutes the first evidence for a sole presence of monazite as LREE-bearing phase in strongly peraluminous PGD from the Grenville Province.

Keywords: Grenville Province; Peraluminous; Pegmatitic Granite; LREE; Whole-rock geochemistry; Allanite/Monazite

1. Introduction

Granitic pegmatites host numerous metallic occurrences, mostly rare-metals such as U-Th, Nb-Ta, Y, Rare Earth Elements (REE), Ti, Zr, Be, Li, Cs, Mo, Rb, B, P, Pb, F. Due to their small sizes, REE-rich granitic pegmatites are generally not considered as good economic target when compared to their plutonic counterparts, and have thus not received the same attention (e.g. Ercit, 2005; Goodenough et al., 2016; London, 2016). However, the worldwide overwhelming occurrences of REE-bearing granitic pegmatites may potentially represent important sources of REE and are to be included in the further global investigations of the REE metallogenic system. The lack of detailed field descriptions, whole-rock and mineralogical compositions, as well as structural data for the pegmatitic bodies and their host and country rocks prevent a good understanding of the source, the formation and the concentration of REE-bearing pegmatites (Dill, 2015; Ercit, 2005). Classification schemes, such as the NYF (Nb-Y-F) classes of Černý et al. (2012) or the "chessboard" scheme of Dill (2010), generally depict REE-rich granitic pegmatites as being derived from an alkaline melt fractionation (Dill, 2010, 2015). However, in some cases (e.g. in the Grenville Province) where the lack of coeval granitic pluton is not necessarily due to a lack of outcrops, a derivation of REE-rich granitic pegmatites from partial melting of a crustal/sub-crustal component is generally inferred, but not clearly demonstrated (Ercit, 2005 and references therein).

With this in mind, the Proterozoic Grenville Province, mainly exposed in Quebec and Ontario (Canada, Fig. 1), offers the possibility to study numerous magmatic REE occurrences, mainly late- to post-Grenvillian in age, and associated with a large spectrum of magmatic environments including nepheline-syenite (e.g. Saint-Honoré, Crevier, Bergeron, 1980; Gauthier and Chartrand, 2005; Groulier, 2013; Sangster et al., 1992), carbonatite (e.g. Niobec, Crevier, Bergeron, 1980; Groulier, 2013), as well as numerous granitic pegmatites (e.g. Ayres

and Černý, 1982; Černý, 1990; Ercit, 2005; Ford, 1982; Lentz, 1996; Masson and Gordon, 1981; Moukhsil et al., 2014). Other "non-magmatic" REE occurrences are described in this province such as the metasomatic mineralization of Kipawa or the Kwyjibo IOCG-type deposit, with a REE mineralization dated at ca. 1030 Ma (Saucier et al., 2013; van Breemen and Currie, 2004) and ca. 985-970 Ma (Gauthier et al., 2004; Perreault and Lafrance, 2015 and references therein), respectively.

During the past few decades, several studies investigated the distribution, mineralogy and petrogenesis of granitic pegmatites from the Grenville Province (Ayres and Černý, 1982; Černý, 1990; Fowler and Doig, 1983; Lentz, 1996, 1991; Masson and Gordon, 1981). They typically comprise with U-Th, Nb-Ta, Y, Ti, Zr, REE, Be, Mo, P, Pb, F (Ayres and Černý, 1982; Černý, 1990; Fowler and Doig, 1983; Gauthier and Chartrand, 2005; Lentz, 1996; Masson and Gordon, 1981). They are generally interpreted as representing a silicate melt extracted from partially molten rocks between ca. 1.1 to 0.9 Ga during the late stages of major intrusive events coeval with the end of Grenvillian high-grade metamorphism based on (i) the lack of coeval granitic pluton, (ii) their magmatic and undeformed texture, and (iii) their discordant and intrusive nature in brittle zones within competent units (Ayres and Černý, 1982; Ercit, 2005; Lentz, 1991; Lumbers, 1964; Masson and Gordon, 1981). Accordingly, the presence of REE-enriched pegmatitic granite dykes (further designated as 'PGD') in the Grenville Province raises the question of (i) the source of these magmas and (ii) the geodynamic context that prevailed during their emplacement. Were these granitic magmas produced by partial melting of the thermally relaxed orogenic root composed of reworked Archean and/or Proterozoic pre-existing continental crust, or do they correspond to extremely differentiated mantle melts produced by decompression owing to post-orogenic extension?

The previous studies mentioned above have been mainly focused on the western parts of the Grenville Province and, to our knowledge, no REE-rich PGD have been described in

the central part of the Grenville Province (Fig. 1). A recent campaign of cartography in the Lac Okaopéo region conducted by Moukhsil et al. (2014) (Figs. 2-3) has led to the identification of seven REE magmatic occurrences associated with discordant PGD intrusive either in migmatitic paragneisses or in metaplutonic complexes (Fig. 3, Table 1, Moukhsil et al., 2014). These PGD have ΣREE contents ranging from 1418 to 9242 ppm (this study, Table 2) and represent new REE occurrences in the Grenville Province. The present paper is dedicated (i) to describe the field relationships between the various PGD and their host rocks to constrain their structural framework; (ii) to characterize their petrography and whole-rock geochemistry, allowing to discuss potential sources and processes responsible for their emplacement and concentration; and (iii) to constrain the timing of REE mineralization by LA-ICP-MS U-Pb dating on monazite in order to replace these PGD in the tectonic-metamorphic framework of the Grenvillian Orogeny. Finally, these results will be compared to other LREE-enriched granitic pegmatites reported elsewhere.

2. Geological framework

2.1. The Grenville Orogenic Belt

The study area is located in the central Grenville Province (Fig. 1b), which mainly crops out along the southeastern Canadian Shield (Fig. 1a). It results from a long history of tectonic-magmatic accretion through the Mesoproterozoic and subsequent continent-continent collision designated as the Grenvillian Orogeny *sensu stricto* (e.g. Carr et al., 2000; Dunning and Indares, 2010; Gower and Krogh, 2002; Rivers et al., 2012; Tucker and Gower, 1994).

FIGURE 1

The two main tectonometamorphic domains of the Grenville Province, namely the Allochthonous and the Parautochthonous belts recorded the Grenvillian Orogeny as two distinct phases. The Allochthonous Belt (Fig. 1b) is made of terranes that originated outboard

of, and were accreted to Laurentia during the Mesoproterozoic (Rivers et al., 2012). The underlying Parautochthonous Belt (Fig. 1b) corresponds to rocks of the Superior Province and its cover sequence or to previously accreted arc that were reworked during the Grenvillian Orogeny (Rivers et al., 1989, 2012). The Allochthonous and the Parautochthonous belts are separated by the southeast-dipping and orogen-scale high-grade shear zone designated as the Allochthon Boundary Thrust (ABT, Figs. 1b, 2). The "Ottawan" crustal thickening phase is first of the Grenvillian Orogeny, and was characterized by the development of a hot ductile crust underneath an orogenic plateau ("Orogenic Lid", Fig. 1b) with a lower limit inferred to be the ABT, between ca. 1090 and 1020 Ma in the Allochthonous Belt (e.g. Carr et al., 2000; Dunning and Indares, 2010; Indares et al., 2000; Rivers, 2008, 1997; Rivers et al., 2012). This plateau is inferred to have collapsed on itself after the Ottawan phase resulting in the formation of several normal-sense shear zones commonly associated with the emplacement of PGD, and assisted by the intrusion of AMCG suites that resulted in weakening and lubricating of the shear zones (Ketchum et al., 1998; Rivers, 2012; Rivers and Schwerdtner, 2015; Soucy La Roche et al., 2015). Renewed convergence during the relatively short-lived Rigolet phase (1005-960 Ma, Rivers, 2009) resulted in foreland-ward propagation of Grenvillian thrusting and high-grade metamorphism, the northwest limit of which is the Grenville Front (Fig. 1), an orogen-scale, southeast-dipping shear zone that was active during the Rigolet orogenic phase (Krogh, 1994; Rivers et al., 1989; Rivers, 2008, 2009). Synkinematic PGD and sills were intruded at upper and lower structural levels of the Parautochthonous and Allochthonous belts, respectively, between 993 and 961 Ma during this later phase on the south shore of the Manicouagan Reservoir (Fig. 2, Jannin et al., In press).

North of Manicouagan Reservoir, the Ottawan tectonic phase reached a metamorphic peak at ca. 1450 MPa and 860-900^{o}C between ca. 1080-1040 Ma (Indares et al., 1998; Indares and Dunning, 2001; Lasalle et al., 2013; Lasalle and Indares, 2014; Rivers et al., 2002) in

kyanite-bearing rocks from the Manicouagan Imbricate Zone (MIZ, central Grenville, Fig. 2), a high-grade nappe of Paleoproterozoic and Mesoproterozoic rocks of the Allochthonous H*P* Belt (aH*P*, Fig. 1b). It was followed by the exhumation of the MIZ over a crustal-scale ramp structurally above the Parautochthonous Belt at ca. 1100 MPa and 870^{o}C between ca. 1040-1030 Ma (Indares et al., 1998; Indares and Dunning, 2001; Lasalle et al., 2013; Lasalle and Indares, 2014; Rivers et al., 2002), and by the subsequent pervasive intrusion of mantle-derived magmas in the thickened orogenic crust (e.g. Dunning and Indares, 2010; Hynes et al., 2000; Indares et al., 2000; Indares and Dunning, 2004). South of the Manicouagan reservoir (just north of our study area; Fig. 2), however, peak metamorphic conditions at sillimanite-grade conditions reached ca. 950 MPa and 850^{o}C between ca. 1080 and 1040 Ma (Dunning and Indares, 2010; Lasalle et al., 2014; Lasalle and Indares, 2014). In the Parautochthonous Belt south of the reservoir, granulite-facies peak metamorphic conditions of ca. 1500 MPa and 850^{o}C were reached between ca. 1005-980 Ma (Hynes et al., 2000; Jordan et al., 2006; Rivers, 2009; Rivers et al., 2012; van Gool et al., 2008) in metapelites from the Knob Lake Group Paleoproterozoic sequence of the Gagnon Terrane that unconformably overlie the Laurentian Archean basement (Parautochthonous Belt, Fig. 2, Dunning and Indares, 2010; Hynes et al., 2000; Rivers, 1980; Rivers et al., 1989). A recent study indicated that high-grade deformation continued until at least ca. 986 Ma (but could be as young ca. 961 Ma) as rocks of the upper and lower parts of the Parautochthonous and the Allochthonous belts, respectively, were likely flowing as an orogenic channel (Jannin et al., In press).

FIGURE 2

2.2. The Lac Okaopéo lithotectonic units and structures

The Lac Okaopéo region is located south of the MIZ and of the Daniel-Johnson dam (Manic-5, Fig. 2). The various lithotectonic units identified in this region (Gobeil et al., 2002;

Moukhsil et al., 2014, 2013a, 2013b, 2012, 2009, 2007) belong to the Allochthonous M*P* Belt of the Grenville Province, structurally above the Allochthon Boundary Thrust (ABT, Fig. 2).

FIGURE 3

2.2.1. PGD host rocks

The PGD investigated in this study are hosted either in paragneisses or in two distinct metaplutonic suites, designated as the Bardoux and the Castoréum. The paragneisses from the Plus-Value Complex mainly crop out in the northwestern part of the region (Fig. 3) and are the oldest protolith in the region with a deposition age between 1765 to 1497 Ma (Augland et al., 2015; Lasalle et al., 2013; Moukhsil et al., 2014, 2013b).

The Bardoux plutonic suite (Fig. 3) is a greyish metagranite dominated by a metaluminous I-type to minor peraluminous S-type signature with millimetric garnet and biotite completed with phenocrysts (up to 5 cm) of K-feldspar (microcline) showing locally rapakivi texture, and containing some enclaves of diorite, monzonite and monzodiorite, that represent continental-arc granitoids emplaced into the Laurentian margin (Augland et al., 2015; Moukhsil et al., 2014, 2012). It has been dated at 1487.6±6.8 Ma in the Lac du Milieu region (U-Pb on zircon, Moukhsil et al., 2012), and at 1497±5 Ma in the Lac Okaopéo region (U-Pb on zircon, Augland et al., 2015). The Castoréum Plutonic Suite, which is intrusive in the Plus-Value Complex and in the Bardoux Plutonic Suite (Fig. 3), is dominated by a facies of homogeneous porphyric to porphyroclastic metagranite with a metamorphic fabric delineated by the preferred orientation of biotite, hornblende and recrystallized or fractured feldspar phenocrysts (Moukhsil et al., 2014, 2013b). It is associated with minor charnockite, mangerite, granitic gneisses, and metatonalite (Moukhsil et al., 2014, 2013b). It has been dated at 1393±8 Ma (U-Pb on zircon) and emplaced in an arc-setting (Augland et al., 2015).

2.2.2. Other lithotectonic units exposed in the Lac Okaopéo region

The Lac Okaopéo region displays other lithotectonic units besides the ones intruded by the PGD (Fig. 3). All are younger than the Plus-Value Complex paragneisses and the Bardoux Plutonic Suite but their emplacement ages spread over the pre-Grenvillian and Grenvillian history. Pre-Grenvillian units include granitic to dioritic orthogneisses, metamangerite and metagranite. As they were emplaced between 1450 Ma and 1100 Ma (Augland et al., 2015; David et al., 2009; Gobeil et al., 2002; Moukhsil et al., 2007, 2012, 2013a, 2013b, 2014), their emplacement, encompasses most of the Mesoproterozoic evolution of the Province from the late-Pinwarian (ca. 1470-1450 Ma, Ketchum et al., 1994; Tucker and Gower, 1994) to the post-Elzevirian (ca. 1245-1225 Ma, Rivers et al., 2012). Several Grenvillian units are coeval with the Ottawan peak of high-grade metamorphism and include granitic to quartz monzodioritic orthogneisses, monzonitic to granitic slightly deformed plutons, and undeformed mafic rocks (David, 2006; Dunning and Indares, 2010; Moukhsil et al., 2007, 2009, 2013b, 2014). Late-Ottawan units include the Berté anorthosite intrusive in the Renwick Mangerite; the weakly deformed metaluminous mangerite and charnockite±leuconorite±granite from the Céline Plutonic Suite (undated), ascribed to the volcanic arc granite domain; the Sabot Mangerite (ca. 1016-1017 Ma); and the high-alkalic mangerite±gabbro±syenite from the Okaopéo Plutonic Suite (1014.6±2.1 Ma) (Gobeil et al., 2002; Moukhsil et al., 2007, 2009, 2013a, 2013b, 2014).

3. Sampling and analytical methods

3.1. Sampling

The seven PGD sampled for this study are accessible by gravel roads branching from the 389 highway, from Baie-Comeau to the Daniel Johnson dam (Manic-5, Figs. 2-3). They are located in the northwestern part of the studied region (NTS sheets 22K/07 and 22K/10, Figs. 2-3, Table 1), and are aligned along a north to south trend (Fig. 3, Moukhsil et al., 2014). The studied PGD are mainly composed of quartz+K-

feldspar+plagioclase+biotite±monazite/allanite (Figs. 4, 6-7, Appendices A-B). Their color and mineralogy are correlated to the nature of the intruded lithologies. Dykes hosted in paragneisses of the Plus-Value Complex are whitish and contain monazite [$(Ce,La,Nd,Th)PO_4$] as the LREE-bearing phase (outcrops 13-AM-07, -10, -13 and 13-TC-5008, Figs. 6, 8-10), while those hosted in metaplutonic complexes of the Bardoux and Castoréum Plutonic Suites are pinkish (fresh color) and contain allanite [$(Ce,Ca)_2(Al,Fe^{3+})_3(SiO_4)_3(OH)$] (outcrops 13-TC-5072, 13-FS-1202 and 13-AE-2149, Figs. 7, 11-12).

3.2. Whole rock geochemistry

Whole-rock geochemistry of the most REE enriched facies of the PGD identified on each outcrop was performed by Actlabs (Ancaster, Ontario). Samples were chosen according to the abundance of REE phases, i.e. monazite and allanite, and using a RS125 scintillometer allowing for the identification of LREE-rich and LREE-poor facies as they are hosted in U-Th-bearing phases. Powdered samples were prepared by Li-metaborate or -tetraborate. Major elements were analysed by inductively coupled plasma - atomic emission spectroscopy (ICP‑AES), and trace elements by inductively coupled plasma - mass spectrometry (ICP‑MS). Results are reported in Table 2. In the present contribution, we report original geochemical data and we include an analysis from Moukhsil et al. (2014) for sample 13-AE-2149 (Tables 1-2).

3.3. Electron microprobe (EMP)

Element composition and chemical maps were obtained by the Electron Microprobe (EMP) method using a Cameca computer-controlled SX-100 (GeoRessources, Nancy) equipped with a wavelength dispersive spectrometer (WDS).

For quantitative analyses and chemical mapping of monazite from the 13-AM-13 and the 13-TC-5008 PGD, major and trace elements (Si, P, Ca, Y, La, Ce, Pr, Nd, Sm, Gd, Pb, Th, U) were measured using an accelerating voltage of 20 kV and a beam current of 100 nA. Peak counting time was set to 120 s for Pb, 100 s for U and 20 s for the others elements. Results are reported in Table 3. Chemical mapping were realized at 15 kV and 100 nA, using a stage scanning mode. Dwell time per pixel was adjusted to 30 ms and pixel step range from 0.3 to 0.9 µm. The chosen X-ray lines were: Ca*Kα*, Th*Mα*, U*M*β, Y*Lα* and Ce*Lα*. Maps are reported in Fig. 9.

For quantitative analyses of allanite from the 13-TC-5072 and the 13-FS-1202 PGD, major and trace elements (F, Mg, Al, Si, P, K, Ca, Ti, Mn, Fe, Sr, Y, La, Ce, Pr, Nd, Sm, Gd, Pb, Th, U) were measured using an accelerating voltage of 20 kV and a beam current of 100 nA. Peak counting time was set to 120 s for Pb, 100 s for U and 20 s for the others elements. Results are reported in Table 4.

3.4. U-Pb dating on monazite using Laser Ablation-Inductively Coupled Plasma-Mass Spectrometry (LA-ICP-MS)

U-Pb geochronology of monazite grains from two PGD (13-AM-13 and 13-TC-5008) was conducted directly on thin sections at Géosciences Rennes (France) by in-situ laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) using a ESI NWR193UC Excimer laser coupled to a quadripole Agilent 7700x ICP-MS.

The signals of ^{204}(Pb+Hg), ^{206}Pb, ^{207}Pb, ^{208}Pb and ^{238}U masses have been acquired during the course of the analyses. The ^{235}U signal is calculated from ^{238}U on the basis of the ratio $^{238}U/^{235}U = 137.88$. Single analyses consisted of 20 s of background integration followed by 60 s integration with the laser firing followed by a 10 s delay to wash out the previous sample. Spot diameters of 10 µm associated with repetition rates of 2 Hz and a laser fluency

of 6.5 J.cm^{-2} were used during the present study. For more information on the settings of the instrument, see Ballouard et al. (2015) and the Appendix D for details and operating conditions of the LA-ICP-MS measurements. Data reduction was carried out with the GLITTER® software package developed by the Macquarie Research Ltd (Van Achterbergh et al., 2001). Raw data were corrected for Pb/U laser-induced elemental fractionation and for instrumental mass discrimination by standard bracketing with repeated measurements of the Moacir monazite standard (Gasquet et al., 2010). To control the reproducibility and accuracy of the corrections, repeated analyses of the Manangoutry monazite standard (554.8±4.2 Ma; MSWD = 0.94, n = 8 for the 13-AM-13 sample; 554.4±3.4 Ma; MSWD = 0.94, n = 8 for the 13-TC-5008 sample; TIMS age 555±2 Ma; Paquette and Tiepolo, 2007) were treated as unknown. No common Pb correction was applied. Concordia diagrams were generated using Isoplot/Ex (Ludwig, 2001). All errors given in Table 5 are listed at 1 sigma.

4. Outcrop description and detailed mapping

4.1. Monazite-bearing PGD (paragneisses-hosted)

Four of the REE occurrences associated with PGD identified by Moukhsil et al. (2014) intrude migmatitic paragneisses of the Plus-Value Complex (Fig. 3). An example of detailed mapping of a monazite-bearing PGD (13-AM-13 outcrop) is provided in Fig. 4, and detailed description and mapping for each of the monazite-bearing outcrops are provided in Appendix A. Structural measurements of the dykes' walls and of the foliation of the host rocks are indicated for each outcrop in Appendix C.

FIGURE 4

To the north of the studied area, PGD are exposed within small (a few square meters in surface) and flat lying outcrops (Fig. 6a) or steep-dipping outcrop along a gravel road. They are made of decimeter- to decameter-sized single dyke bodies with steeply dipping to

subvertical walls trending N/S to locally NW/SE or NE/SW that dominantly plunge towards south, and are strongly (Fig. 6b) to slightly (Fig. 6c) discordant to the foliation of their host (Fig. 5a). Stockscheider-like textures delineate the contact between the 13-AM-07 PGD and the intruded paragneisses (Fig. 6b). All contacts are slightly (over a few millimeters, Fig. 6b) to locally diffuse (outcrop 13-TC-5008, Fig. 6c) and do not correspond to fractures crosscutting the host-rock minerals (Fig. 6c). These PGD display various facies that are (i) fine grained (1 mm to over 1 cm, Fig. 6b and d) with garnet and sub-euhedral monazite (Figs. 6e, f), (ii) intermediate, (iii) coarse-grained (sometimes over 3 cm, Fig. 6d) dominated by quartz and feldspar with minor biotite, and (iv) pegmatitic dominated by quartz+feldspar±biotite (Fig. 6g) with very few accessory phases, no garnet and few monazite crystals. The transition between the fine- and coarse-grained facies is diffuse but is locally underlined by biotite aggregates (Fig. 6d). Locally, skeletal biotite (up to 15 cm crystals) are arranged as an arborescent texture (Fig. 6h). Up to ca. 20 cm centimeters wide quartz aggregates are expressed with no identifiable link with any of the previous facies (Fig. 4).

FIGURE 5

FIGURE 6

These PGD with monazite as the REE-hosting mineral, will further be referred as *'monazite-bearing'* (or *'Mnz-bearing'*) *PGD.*

4.2. Allanite-bearing PGD (metaplutonic complexes-hosted)

Three of the REE occurrences associated with PGD identified by Moukhsil et al. (2014) intrude the metaplutonic complexes of the Bardoux or the Castoréum Plutonic Suite (Fig. 3). Detailed mapping and description for each of the allanite-bearing outcrops are provided in Appendix B and structural measurements of the dykes' walls and of the foliation of the host rocks are indicated for each outcrop in Appendix C.

Outcrops 13-TC-5072, 13-FS-1202 and 13-AE-2149 are either dome shaped (Fig. 7a), flat lying or large steep-dipping (Fig. 7e). Two of these outcrops (13-TC-5072 and 13-FS-1202) are made of decimeter- to meter-sized dyke swarms with steeply dipping to subvertical walls trending NW/SE to locally N/S or NE/SW that plunge variably towards north and south, and are slightly to strongly discordant to the foliation of their host metamonzogranite and quartz metamonzodiorite (Fig. 5b), respectively. The contacts of these two dykes with their host is slightly diffuse (over a few millimeters, Fig. 7c). One outcrop (13-AE-2149), is made of a main shallow dipping dyke oriented NE/SW that plunges towards the north, in textural continuity to granitic veins concordant/discordant to the foliation of the host metamangerite (Figs. 5b, 7e-f). This dyke is slightly discordant to locally sub-concordant to the foliation of its host rock (Fig. 5b) and locally show a very diffuse contact with its host rock at its lower contact (Fig. 7g). None of the contacts of the allanite-bearing PGD correspond to fractures crosscutting the host-rock minerals (Figs. 7c and g).

The metamonzogranite-hosted PGD (13-TC-5072) typically display a fine-grained quartz+feldspar±biotite facies at the contact, with northern boundaries usually marked by K-feldspar phenocrysts (Fig. 7c), and an increasing grain size towards the allanite-rich pegmatitic core that are delineated by biotite aggregates (southern boundary for the dyke represented in Fig. 7c). Allanite from this outcrop may reach several centimeters (Figs. 7c-d). When zoned, the quartz metamonzodiorite-hosted PGD (13-FS-1202) display an internal layering marked by coarse (over 3 cm) allanite-rich and barren facies alternating with fine-grained (0.1-3 cm) allanite-rich facies (Fig. 7b). The metamangerite-hosted PGD (13-AE-2149) is a ca. 1 m wide dyke (Fig. 7e), which displays diffuse contacts with its host rock, the lower being more diffuse than the upper (Fig. 7g). Upper and lower contacts are marked by ca. 20 cm and ca. 45 cm wide pegmatitic facies (some grains being over 10 cm in size) respectively, composed of quartz+feldspar±disseminated allanite phenocrysts. The latter are

335 oriented with their long axis perpendicular to the contact (Fig. 7g). The core of the dyke is a
336 layered fine-grained facies with ca. 30 cm long quartz+K-feldspar-rich lenses that alternate
337 with quartz-plagioclase-rich lenses (Fig. 7g).

338 **FIGURE 7**

339 These PGD with allanite as the REE-hosting mineral, will further be referred as
340 *'allanite-bearing'* (or *'Aln-bearing'*) *PGD.*

341 **5. Detailed petrography of the monazite- and allanite-bearing PGD**

342 **5.1. Petrography of the monazite-bearing PGD (paragneisses-hosted)**

343 All monazite-bearing PGD are dominated by a quartz+K-feldspar+plagioclase±biotite
344 assemblage (Fig. 8a), with a grain size spreading from millimeter to several centimeters (up to
345 5 cm in some facies). It is completed with minor garnet, zircon and monazite that are more
346 abundant in the finest grained facies, and accessory rare pyrite and Ti-oxides. All facies show
347 a magmatic texture and lack evidence for solid-state deformation (Fig. 8a).

348 **FIGURE 8**

349 The monazite crystals from paragneisses-hosted PGD have been investigated in two
350 PGD (the 13-AM-13 and the 13-TC-5008, Figs. 8a-c, 9). In both cases, monazite is expressed
351 as pristine sub-millimetric to several millimeters wide crystals that do not show any signs of
352 corrosion/dissolution. A main difference between monazite crystals from these two samples
353 lies in their inner textures and composition (Figs. 9-10, Table 3).

354 **FIGURE 9**

355 Monazite grains from the 13-AM-13 PGD show oscillatory zoning with a *LREE(Ce)-*
356 *rich* core surrounded by several overgrowths with a composition grading toward a *Th-Si-rich*
357 pole (Figs. 9a-c). These zones display monazite-(Ce) compositions that shift towards

358 monazite-(La) compositions with increasing proportion of Th and Si (Fig. 10a) that is
359 consistent with the concurrent increase in huttonite end-member (from 3.78 % to 12.27 %,
360 Fig. 10b, Table 3), where Th or U + Si = REE + P (Spear and Pyle, 2002). The proportion of
361 brabantite (from 8.66 % to 9.62 %) remains quite stable (Fig. 10b, Table 3).

362 Monazite grains from the 13-TC-5008 PGD are rather homogeneous or weakly zoned
363 as expressed in SEM and X-ray maps. Chemical zoning consists of three zones that grade
364 from a *LREE(Ce)-rich* to a *Th-Si-rich* composition toward the grain boundaries as identified
365 in X-ray maps (Figs. 9d-f, Table 3). The compositions of all the grains are clustered into the
366 monazite-(Ce) field (Fig. 10c) as marked by the quite stable P_2O_5, and REE oxides contents
367 (Table 3) from *LREE(Ce)-rich* zones to *Th-Si-rich* overgrowths. A slight increase in SiO_2 and
368 ThO_2 is consistent with the increase in huttonite end-member (from 4.02 % to 5.39 %, Fig.
369 10d). The proportion of brabantite (from 2.77 % to 3.37 %) remains quite stable (Fig. 10d,
370 Table 3). Plotted in a Th+U+Si vs REE+Y+P diagram, the three investigated zones cluster
371 and spread along a narrow range of the huttonite substitution curve (Fig. 10d).

372 **FIGURE 10**

373 Monazite-bearing PGD also comprise sub-euhedral zircon grains (up to 1-1.5 mm, Fig.
374 8b) that may represent up to ca. 1% of the whole assemblage, mainly in fine grained to
375 intermediate facies. Late-magmatic Th-U(±REE) silicates (Fig. 8c) are present as interstitial
376 few micrometers wide bands in the vicinity of or as filling fractures of monazite crystals.
377 Finally, sericite is expressed as an alteration product of feldspar (K-feldspar and plagioclase,
378 Fig. 8d).

379 **5.2. Petrography of the allanite-bearing PGD (metaplutonic complexes-hosted)**

380 All allanite-bearing PGD are dominated by a quartz+K-feldspar+plagioclase±biotite
381 (Figs. 11a-c) assemblage with a grain size ranging from millimeter to several centimeters

(over 10 cm in some pegmatitic facies, outcrop 13-AE-2149). This assemblage is completed with zircon and allanite, and rare apatite (some grains are present in the pegmatitic facies of the 13-AE-2149 outcrop). The abundance of accessory minerals is not correlated with the grain size. All facies display a magmatic texture and lack evidence for solid-state deformation (Figs. 11a-c).

FIGURE 11

The textural characteristics of allanite from metaplutonic complexes-hosted PGD depend on the host granite. Allanite crystals were investigated in the 13-TC-5072 and the 13-FS-1202 samples and in both cases are sub-euhedral and sub-millimetric to several millimeters wide (Figs. 6b-d, g, 11b-c).

Allanite grains from the 13-TC-5072 PGD show an oscillatory zoned core, further designated as '*Aln*$_1$', corroded and crosscut by an overgrowth of a second generation of intermediate composition allanite, further designated as '*Aln*$_2$' (Fig. 11b), that forms the sub-euhedral shape of allanite phenocrysts. It is surrounded by an alteration rim (Fig. 11b). These three zones cluster as typical allanite compositions plotted in the REE vs Al diagram (Fig. 12a) of Petrík et al. (1995) and display quite similar compositions, except for the decrease in FeO (from 11.11 to 9.76 wt.%) content from the Aln_1 cores to the alteration rims (Table 4).

Allanite grains from the 13-FS-1202 PGD display internal patchy zoning between '*LREE(Ce)-rich*' and '*Fe-Ca-LREE(Ce)-rich*' zones (Fig. 11d). They are surrounded by an alteration rim (Figs. 11c-f). The three zones plot between the epidote and allanite composition in the REE vs Al diagram (Fig. 12b) of Petrík et al. (1995). The Fe-Ca-LREE(Ce)-rich zone displays the most allanite-like composition, whereas the alteration rim is marked by a shift towards the epidote composition (Fig. 12b) associated with an increase in SiO_2 and a decrease in LREE (Table 4).

406 **FIGURE 12**

407 Allanite-bearing PGD also contain sub-euhedral zircon grains (up to 1-1.5 mm, Figs.
408 11c and d) that may represent up to ca. 1% of the whole assemblage, mainly in fine to coarse
409 grained facies. Late-magmatic Ca±REE carbonates or silicates are present as interstitial thin
410 bands (a few micrometers wide) in the vicinity of or in fracture of allanite crystals (Figs. 11e-
411 f). Finally, sericite is expressed as an alteration product of feldspar (K-feldspar and
412 plagioclase, Figs. 11a and c).

413 **6. Whole-rock geochemistry of the monazite- and allanite-bearing PGD**

414 **6.1. Geochemistry of the monazite-bearing PGD (paragneisses-hosted)**

415 Three of the four monazite-bearing PGD (samples 13-AM-07, 13-AM-10 and 13-TC-
416 5008) display typical granitic composition with a SiO_2 content of 71.03 wt.%, 70.80 wt.% and
417 70.79 wt.% respectively (Table 2), and a strong peraluminous character (Fig. 13a) as marked
418 by their (i) ASI (Aluminum Saturation Index, ASI = Al/(Ca – 1.67 x P + Na + K) Frost et al.,
419 2001; Shand, 1943), (ii) A/CNK (A/CNK = Al/(Na + K + Ca/2), Shand, 1943), and (iii) A/NK
420 (A/NK = Al/(Na + K), Shand, 1943) above 1.19, 1.27 and 1.55 respectively (Table 2). In
421 contrast, one monazite-bearing PGD (13-AM-13) does not display a typical granitic
422 composition as its SiO_2 content is down to 60.24 wt.% (Table 2). This low content is
423 associated with the highest Al_2O_3, CaO and Na_2O contents of 18.58 wt.%, 3.10 wt.% and 4.02
424 wt.% respectively, and a low K_2O content of 4.36 wt.% leading to the highest ASI ratio of the
425 monazite-bearing serie at 1.36 (Table 2) that corresponds to a strongly peraluminous signature
426 (Fig. 13a).

427 All the monazite-bearing samples display high ΣREE content ranging from 1418 to
428 7048 ppm (Table 2). Their REE patterns are strongly fractionated in LREE over HREE (Fig.
429 13b), as evidenced by the La_N/Yb_N ratios ranging from 784 to 938 (Table 2), and more or less

developed Eu negative anomaly (Fig. 13b), which intensity increases with the ΣREE content, as marked by decreasing Eu/Eu* from 0.72 down to 0.14 (Table 2). The ΣREE content is also associated with (i) increasing U and Th contents (up to 19.10 and 1300 ppm respectively, Fig. 13c, Table 2) and Nb/Ta ratio (up to 56 with Nb ranging from 5.60 to 21 ppm and Ta ranging from 0.10 to 0.40 ppm, Fig. 13e, Table 2), (ii) increasing Na_2O, CaO and P_2O_5 contents (up to 4.02, 3.10, 0.40 wt.% respectively, Figs. 13d and f, Table 2), and (iii) decreasing K_2O content (down to 4.36 wt.%, Fig. 13d, Table 2). The ΣREE content of monazite-bearing PGD is not linked to the $Fe_2O_{3\ (total)}$ nor MgO contents (Fig. 13g, Table 2). The Zr/Hf ratios are quite stable (ranging from 36 to 44, Fig. 13e, Table 2) with Zr ranging from 195 to 1480 ppm and Hf ranging from 4.40 to 41.50 ppm (Fig. 13e, Table 2).

FIGURE 13

6.2. Geochemistry of the allanite-bearing PGD (metaplutonic complexes-hosted)

Two of the three allanite-bearing PGD (samples 13-TC-5072 and 13-FS-1202) have typical granitic composition with a SiO_2 content of 70.27 wt.% and 70.85 wt.% respectively (Table 2), and a strong peraluminous character (Fig. 13a) as marked by their ASI, A/CNK, and A/NK over 1.18, 1.24 and 1.64 respectively (Table 2). In contrast, one of the PGD (sample 13-AE-2149) does not display a typical granitic composition as its SiO_2 content is down to 55.84 wt.% (Table 2). This low content is associated with the highest Al_2O_3, CaO, Na_2O contents of 15.05 wt.%, 5.54 wt.%, 4.28 wt.% respectively, and a low K_2O content of 1.93 wt.%, leading to the lowest ASI and A/CNK ratio of the allanite-bearing serie at 1.08 and 0.87 (Table 2) that corresponds to a weakly peraluminous signature (Fig. 13a).

All the allanite-bearing samples display high ΣREE content ranging from 2393 to 9242 ppm (Table 2). The REE patterns of the 13-TC-5072 and 13-FS-1202 samples are strongly fractionated in LREE over HREE (Fig. 13b), as evidenced by the La_N/Yb_N ratios

ranging from 261 to 619 (Table 2). The REE pattern of the low-SiO_2 PGD (13-AE-2149 sample) is more enriched in HREE and displays a less fractionated pattern, as marked by its lower La_N/Yb_N ratio of 28 (Table 2). The intensity of the negative Eu anomaly increases with the ΣREE content as shown by decreasing Eu/Eu* from 0.36 down to 0.12 (Table 2). The ΣREE content is also associated with (i) increasing U and Th contents (up to 30.30 and 766 ppm respectively, Fig. 13c, Table 2), (ii) increasing Na_2O, CaO, $Fe_2O_{3\ (total)}$ and MgO contents (up to 4.28, 5.54, 12.42 and 0.85 wt.% respectively, Figs. 13d and g, Table 2), and (iii) decreasing K_2O content (down to 1.33 wt.%, Fig. 13d, Table 2) and Nb/Ta ratio (down to 41 with Nb ranging from 7.50 to 132 ppm and Ta ranging 0.11 to 3.20 ppm, Fig. 13e, Table 2). The ΣREE content of allanite-bearing granite dykes is not linked to the P_2O_5 content (Fig. 13f, Table 2), nor to the Zr/Hf ratios that remain quite stable (ranging from 35 to 39, Fig. 13e, Table 2) with Zr ranging from 290 to 6340 ppm and Hf ranging from 7.40 to 171 ppm (Fig. 13e, Table 2).

7. U-Pb dating of magmatic monazite

Monazite grains from the paragneiss-hosted 13-AM-13 PGD have been investigated through 25 analyses performed directly on thin sections on 7 different grains. Plotted on a concordia diagram, data define a discordia yielding an upper intercept of 1003.9±4.7 Ma (MSWD = 0.43) if the lower intercept is anchored to 0±0 Ma (Fig. 14a, Table 5). Eleven of these 25 analyses are concordant and define a concordia age (as of Ludwig, 1998) of 996.7±5.3 Ma (MSWD = 0.98, Fig. 14b). Even though the monazite grains from this sample are zoned (Figs. 9a-c, 10a-b), these data do not show any signs of inherited cores with distinctly older ages nor isotopic heterogeneity within a grain as all the data spread on the same discordia and point to a single upper intercept date (Fig. 14a).

The monazite grains from the paragneisses-hosted 13-TC-5008 PGD have been investigated through 22 analyses performed on 9 different grains. Plotted on a concordia diagram, data plot on the concordia curve, and yield a concordia age of 1005.4±4.4 Ma (MSWD = 1.01; Fig. 14c, Table 5). As for the 13-AM-13 PGD, these data do not point to the presence of inherited cores with an older age nor heterogeneity within a grain as all the data plot on the concordia curve (Fig. 14c). This is consistent with the lack of chemical zoning on the studied monazite grains (Figs. 9d-f, 10c-d).

FIGURE 14

8. Discussion

8.1. LREE-rich PGD from the Lac Okapéo region in the frame of the Grenvillian Orogeny

The Grenville Province hosts numerous granitic pegmatites (e.g. Ayres and Černý, 1982; Černý, 1990; Ercit, 2005; Ford, 1982; Fowler and Doig, 1983; Lentz, 1996, 1991; Lumbers, 1979; Masson and Gordon, 1981), mainly in the Central Gneiss Belt, in the Central Metasedimentary Belt, in the Central Granulite Terrain and in the Eastern Grenville (Fig. 1b). They are discordant and intrusive in brittle zones within competent units, show magmatic and undeformed texture, and geochronological constraints evidence for their late-Grenvillian Orogeny timing of emplacement (Ford, 1982; Fowler and Doig, 1983; Lentz, 1996, 1991, Lumbers, 1979, 1964). These granitic pegmatites are assumed to be either derived (i) from partial melting of paragneiss and/or orthogneiss, consistent with the presence of migmatites and the lack of coeval intrusive granitic plutons (e.g. Ayres and Černý, 1982; Lentz, 1996, 1991; Lumbers, 1964; Masson and Gordon, 1981), or (ii) from the differentiation of a melt segregated from a granite at the end of fractional crystallization (Ayres and Černý, 1982; Masson and Gordon, 1981).

The main features of the LREE-rich PGD from the Lac Okaopéo region obtained in this study have been summarized in Table 6. They are discordant to the foliation of their host rocks and present magmatic textures with no macroscopic nor microscopic evidence for solid-state deformation (Figs. 5-7, 8a, d, 11a-c). All of these PGD, to the noticeable exception of one (13-AE-2149 PGD), are steep-dipping dykes with limited diffuse contacts and no interconnection with leucosome (Figs. 5-7) suggesting they are intrusive into the Paleoproterozoic to Mesoproterozoic Plus-Value paragneisses and Bardoux and Castoréum metaplutonic suites, in a late- to post-tectonic regime, as other REE-rich Grenvillian granitic pegmatites (Ercit, 2005; Lentz, 1996, 1991).

The 13-AE-2149 PGD is a shallow-dipping dyke connected to a network of concordant/discordant veins to the foliation of its host layered mangerite (Figs. 5b, 7e-f) suggesting a distinct and shallower source, and/or a different stress regime. The diffuse contact at its lower contact (Fig. 7g) emphasizes a different petrogenetic process which might have involved syn-crystallization fluid expulsion.

Formation of an orogenic plateau between ca. 1080-1050 Ma has been proposed to be related to ductile lateral flow of the orogenic root beneath the ABT at the base of the Orogenic Lid (Fig. 1b, Rivers, 2008). Late-Ottawan gravitational collapse is inferred to have started in the central Grenville Province by ca. 1065 Ma (Rivers and Schwerdtner, 2015; Soucy La Roche et al., 2015) and to have been completed by ca. 1020 Ma in the western part of the Grenville Province, as evidenced by the reworking of the ABT as an extensional shear zone (Ketchum et al., 1998; Rivers, 2008; Rivers et al., 2012). In the central Grenville, normal shear-sense indicators in a 1015 Ma granite (Indares et al., 2000) in the MIZ and the intrusion of mafic to intermediate magmatic rocks, such as the ca. 1015 Ma Okaopéo Plutonic Suite (Fig. 3) that crosscuts the Ottawan metamorphic fabrics, have been attributed to a phase of crustal extension compatible with this model (e.g. Augland et al., 2015; Indares et al., 2000).

Following the poor tectonic record from ca. 1020 to 1005-1000 Ma, the Rigolet orogenic phase at ca. 1005-980 Ma, marked by the deformation and metamorphism of the Parautochthonous Belt structurally below the ABT, is interpreted to represent a short-lived crustal thickening event (e.g. Dunning and Indares, 2010; Jordan et al., 2006; Lasalle et al., 2013). U-Pb dating on magmatic monazite grains from two PGD of the Lac Okaopéo region yield dates of 996.7±5.3 Ma (13-AM-13 PGD, Figs. 14a-b, Table 5) and 1005.4±4.4 Ma (13-TC-5008 PGD, Fig. 14c, Table 5) (see section 7 for details) that are comparable within uncertainty. According to the lack of corrosion of the monazite grains, their oscillatory zoning with no recrystallized domains or their unzoned character, these ca. 1005-1000 Ma concordant dates are interpreted as reflecting their igneous crystallization ages (Crowley et al., 2008) and are therefore attributed to post-Ottawan peak of metamorphism corresponding to the initiation of the Rigolet orogenic phase. These emplacement ages are consistent (i) with the discordant contacts of the dykes to the foliation of their hosts (Figs. 5, 6b, 7c, e-f) and (ii) with the magmatic textures with no evidence for a solid-state deformation nor interconnection with leucosomes (Figs. 6-7, 8a, d, 11a-c). These features suggest a post-tectonic and metamorphic intrusion of the PGD relative to the paragneisses and the metaplutonic complexes of the Allochthonous Belt they intrude and which were affected by the Ottawan orogenic phase (Augland et al., 2015; Moukhsil et al., 2014). This timing of emplacement is similar to the late- to post-Grenvillian Orogeny age of pegmatitic bodies in the western Grenville Province (Fowler and Doig, 1983; Lentz, 1996, 1991, Lumbers, 1979, 1964).

8.2. Potential sources of the LREE-rich PGD from the Lac Okaopéo region

In granitic pegmatite fields reported in the literature, e.g. in Cap de Creus (northeastern Spain, Alfonso and Melgarejo, 2008; Druguet et al., 2014; Van Lichtervelde et al., 2016) or in Gatumba (central Rwanda, Hulsbosch et al., 2014; Melcher et al., 2015), the closest bodies from the sources (usually a granite) (i) are the least evolved, and (ii) contain

biotite but no muscovite nor rare-element minerals (i.e. Li, B, Be, Rb, Sn, Nb-Ta… e.g. Hulsbosch et al., 2014; London, 2016, 2008) or REE mineralization (e.g. Ercit, 2005). In the case of the PGD from the Lac Okaopéo region, the ubiquitous presence of biotite in all the investigated dykes with no muscovite nor other rare elements minerals than monazite or allanite and zircon suggests that they do not represent the last melts that differentiated from the source.

The intrusive contacts of the PGD (Figs. 5, 6b, 7c) and the lack of textural continuity between the PGD and the leucosomes of the host rocks (except for the 13-AE-2149 dyke), are pointing to an origin from a deeper-seated source. This interpretation is corroborated by their emplacement age during the early Rigolet orogenic phase (ca. 1.0 Ga) in host rocks that have recorded deformation and metamorphism during the Ottawan orogenic phase. Furthermore, their pronounced peraluminous signatures (Fig. 13a) are not compatible with a magma derived from the fractionation of the late-Ottawan mafic to intermediate Plutonic Suites of the Lac Okaopéo region, nor of the undated metaluminous volcanic arc granite Céline Plutonic Suite (Augland et al., 2015; Moukhsil et al., 2009, 2013a, 2014).

Jannin et al. (In press) documented that partial melting at a lower structural level than our study area was initiated at least from ca. 1002 Ma at high-pressure in the presence of garnet with pegmatite emplacement taking place between 993 down to possibly 961 Ma. These results confirm that the Parautochthonous Belt experienced the Rigolet crustal thickening phase under granulite facies metamorphism (up to ca. 15 kbar and 850^{o}C between ca. 1005-980 Ma, Jordan et al., 2006), i.e. conditions that are favorable for the partial melting of the Parautochthonous Belt and coeval with the emplacement of the PGD. Nb/Ta ratios of the PGD from the Lac Okaopéo region are very high (ranging from 34 to 58, Fig. 13e, Table 2) and are associated with low (except for the 13-AE-2149 dyke) Nb and Ta contents (up to 21 and 0.40 respectively, Table 2). Such low values are consistent with the lack of Nb-Ta-

bearing minerals in the PGD, and associated with high Nb/Ta are consistent with high-temperature partial melting resulting in a total consumption of biotite from the protolith and the formation of Ti-oxides in the residue that are preferential hosts for Nb and Ta and preferentially fractionate the latter (Stepanov et al., 2014). Phase equilibria modeling of metapelite such as those of the Knob Lake Group indicates that a common partial-melting reaction in high-pressure granulite is Bt + Pl ± Ky = Liq + Grt + Kfs + Qtz + Rt (Gervais and Crowley, 2017). In addition to producing leucosome with zircon depleted in HREE because of their sequestration in garnet, such as those in leucosome of the Parautochthonous Belt (Jannin et al., In press), the growth of peritectic rutile associated with this reaction should produce melt with the Nb-Ta features observed in the investigated PGD.

The strongly peraluminous character of these PGD (Fig. 13a, Table 2) contrast with the metaluminous signature of the western Grenvillian REE-rich granitic pegmatites reported by Lentz (1996) (Fig. 13a, Table 2) and is compatible with their derivation by partial melting of a metasedimentary unit (e.g. Chappell and White, 2001; Cuney, 2014; White and Chappell, 1977). The high La_N/Yb_N ranging from 784 to 938 (monazite-bearing PGD) and from 261 to 619 (13-TC-5072 and 13-FS-1202 allanite-bearing PGD) suggest that these dykes represent melts segregated from a molten crustal component enriched in a HREE-bearing phase, most probably garnet as it is very common in paragneisses especially in those from the Knob Lake Group of the Gagnon Terrane (Bea, 1996; Hönig et al., 2014; Jordan et al., 2006). These features are consistent with the lack of evidence for coeval kilometric scale granitic intrusive body at this stage of the Grenvillian Orogeny and with the results of the great majority of studies dealing with Grenvillian REE-rich granitic pegmatites (e.g. Ercit, 2005; Lentz, 1996, 1991). In addition, it brings evidence that REE-rich granitic pegmatites do not necessarily derive from the fractionation of a granitic intrusive body and that they may be metamorphic in origin as it is proposed by default, especially in the Grenville Province, because of the lack of

an exposed coeval granitic intrusive body (Ercit, 2005). Even though the timing of emplacement and field relationships of the dykes are in favor of a source belonging to the Parautochthonous Belt, whether the molten paragneisses that led to the formation of these dykes belong to the deep Allochthonous (Plus-Value Complex, Figs. 2-3, Moukhsil et al., 2014, 2012) or to the Parautochthonous Belt (Knob Lake Group of the Gagnon Terrane, Fig. 2, e.g. Rivers, 2008) remains an open question.

The 13-AE-2149 allanite-bearing PGD displays quite different features when compared to other PGD such as (i) a shallow-dipping and diffuse contact (Figs. 5b, 7g), (ii) higher Nb and Ta contents of 132 and 3.20 ppm respectively (Table 2), (iii) a weakly peraluminous character (ASI of 1.08, Fig. 13a, Table 2), and (iv) a much lower La_N/Yb_N of 28 (Fig. 13b, Table 2). These features suggest its possible derivation by differentiation of a late-Ottawan garnet/rutile-poor source (Bea, 1996; Hönig et al., 2014; Stepanov et al., 2014) such as the ca. 1015 Ma Okaopéo Plutonic Suite (high-alkalic mangerite±gabbro±syenite) and Sabot Mangerite (Augland et al., 2015; Moukhsil et al., 2014), combined with late-crystallization fluid release and/or an interaction with its pre-Grenvillian host metamangerite during its intrusion.

8.3. Unusual petrogeochemical characteristics of the LREE-rich PGD from the Lac Okapéo region

Previous studies have shown that Grenvillian granitic pegmatites are dominated by quartz+K-feldspar+plagioclase ± a ferromagnesian phase, completed with a variety of other major and minor phases (e.g. pyroxene, amphibole, biotite, titanite, magnetite, sulfides, allanite, zircon, garnet, monazite, pyrochlore-group minerals and U-Th phases, Ercit, 2005; Fowler and Doig, 1983). Grenvillian granitic pegmatites commonly host REE together with other metals such as U-Th, Nb-Ta, Y, Ti, Zr, Be, Mo, P, Pb, F, with no REE-only mineralization described in these occurrences. The mineralogical assemblage of the PGD

626 from the Lac Okaopéo region is dominated by quartz+K-feldspar+plagioclase+biotite, as
627 proposed by Ercit (2005), Ford (1982) and Lentz (1996, 1991), and is completed with zircon
628 and monazite or allanite (Figs. 8-12, Tables 3 and 4). No complementary rare-element
629 minerals have been recognized in the PGD of the Lac Okaopéo region, except for the late but
630 micrometric Th-U(±REE) silicates (Fig. 8c) and the Ca±REE silicates or carbonates (Fig.
631 11e-f) identified in the monazite- and allanite-bearing PGD, respectively, and that represent a
632 negligible part of the whole rock. The accessory phases assemblages, even if not uncommon
633 in worldwide abyssal class pegmatitic bodies (Ercit, 2005), is less diverse than for the rest of
634 the LREE-enriched Grenvillian PGD (Ford, 1982; Lentz, 1996, 1991). Accordingly, the PGD
635 from the Lac Okaopéo region represent the first evidence of magmatic REE-only
636 mineralization in this region.

637 Monazite and allanite crystals from the PGD investigated in this study are monazite-
638 (Ce) and allanite-(Ce) and generally display a core to rim zoning (Figs. 9, 10a, c, 11b, d,
639 Tables 3-4). Monazite crystals from the two investigated PGD present a dominant substitution
640 expressed by the huttonite end-member that is consistent with the concurrent evolution of Th
641 and ΣREE contents (13-AM-13 and 13-TC-5008, Figs. 10b and d, 13c, e.g. Spear and Pyle,
642 2002). Monazite from the 13-TC-5008 PGD are rather homogeneous (Figs. 9d-f, 10c-d)
643 whereas oscillatory zoned monazite from the 13-AM-13 PGD are characterized by a gradient
644 trending towards monazite-(La) from LREE(Ce)-rich cores to Th-Si-rich rims (Figs. 9a-c,
645 10a-b, Table 3). This suggests an evolution of the melt composition during crystallization
646 from LREE-rich towards Th-Si-rich most probably related to the crystallization of zircon, the
647 only LREE-poor/Th-Si-bearing phase present in the dykes (e.g. Bea, 1996; Hanchar et al.,
648 2001). Its crystallization would generate a LREE-rich/Th-Si-poor residual melt, allowing the
649 preferential incorporation of LREE into the monazite lattice and a relatively LREE-
650 impoverished/Th-Si-enriched residual melt after zircon growth is completed. In contrast,

allanite crystals from the 13-TC-5072 and the 13-FS-1202 PGD display distinct textures. Those from the former show oscillatory zoned cores (Aln_1) corroded by overgrowths (Aln_2, Fig. 11b) with stable compositions (Fig. 12a, Table 4). This is most probably related to a new magmatic pulse and not to a significant change in the melt composition. Allanite phenocrysts from the latter however show inner patchy and not oscillatory zoning suggesting a random organization between LREE(Ce)-rich and Fe-Ca-LREE(Ce)-rich zones (Fig. 11d, Table 4). This points to more complex petrogenetic processes than successive growths associated with distinct magmatic pulses. However, a compositional change is recorded in the Fe-poor and in the Si-rich/LREE-poor alteration rims that are expressed on every allanite phenocrysts from the 13-TC-5072 (Fig. 11b) and the 13-FS-1202 (Figs. 11d-e) PGD, respectively (Table 4). According to the lack of corrosion of previous zones associated with no changes in the euhedral shape of the grains, its association with the late-sericitization of feldspar (Fig. 11a, c) and formation of late-Ca±REE carbonates or silicates veinlets (Fig. 11e-f), this alteration is most likely related to magmatic-hydrothermal transition processes. In summary, monazite crystals would record the fractionation of zircon during the course of melt crystallization of paragneisses-hosted PGD marked by syn-zircon growth LREE-rich/Th-Si-poor monazite cores and post-zircon growth LREE-poor/Th-Si-rich zones. In contrast, allanite phenocrysts do not allow to discuss magmatic fractionation but offer insights on the magmatic-hydrothermal transition associated with the formation of allanite alteration rims coeval with late veinlets of carbonates or silicates and most probably with feldspar sericitization.

The empirical relation of monazite in paragneisses-hosted PGD and allanite in metaplutonic-hosted PGD might reflect either (i) an initial geochemical difference between the two granitic series, and/or (ii) interactions of the melt with different rocks during ascent and/or at emplacement level. On the one hand, the former hypothesis is strengthened by (i) the positive correlation between the P_2O_5, CaO and the ΣREE contents (Fig. 13f) in monazite-

bearing PGD, unlike in allanite-bearing, and (ii) the positive correlation between the Fe_2O_3 $_{(total)}$, MgO and the ΣREE contents in allanite-bearing PGD (Fig. 13g). On the other hand, the hypothesis of an interaction between melts and surrounding rocks is supported by the empirical relationship (i) between monazite-bearing PGD and wide outcropping areas of metasediments (3 over 4 PGD hosted in the Plus-Value Complex), and (ii) between allanite-bearing PGD and metaplutonic complexes (2 over 3 PGD hosted in the Bardoux and Castoréum Plutonic Suites) (Figs. 3, 6-7). These suggest that the crystallization of monazite and allanite could be related to interactions of the granitic melt (i) with the more sodic metasedimentary host of the Plus-Value complex for the former, and conversely (ii) with the more calcic igneous rocks of the Bardoux and Castoréum suites for the latter. This hypothesis is consistent with the locally diffuse contact of the 13-TC-5008 monazite-bearing PGD (Fig. 6c) and the very diffuse contact at the lower contact of the 13-AE-2149 allanite-bearing PGD (Fig. 7g). Such a model has been proposed for granitic pegmatites from the southwestern Grenville Province and is designated as “hybridization” by Lentz (1996, 1991), who evidenced bi-metasomatic exchange processes leading to Ca, Fe, Mg±Ti enrichment in the melts and to the crystallization of titanite and allanite. However, (i) the lack of macroscopic mineralogical reaction zone at the contact of most of the dykes with their host rocks, and (ii) the close geographical association of the 13-TC-5008 monazite-bearing and the 13-AE-2149 allanite-bearing PGD (Fig. 3), make the hypotheses of a control of the mineralization by deep interaction between the magma and rocks of distinct chemical composition unlikely. In addition, both monazite- and allanite-bearing samples display a similar positive correlation between the Na_2O, the CaO and the ΣREE contents (Fig. 13d) suggesting that the hypothesis of an initial geochemical difference between the two granitic series is most likely. Therefore we propose that the control of the mineralization either as monazite or allanite observed in the PGD from the Lac Okaopéo may not only be correlated with the activities of Na and Ca as

proposed in the models of Berger et al. (2009) and Budzyń et al. (2011) but by the initial CaO and P_2O_5 contents, and the $Fe_2O_{3\ (total)}$ and MgO, respectively. Exception is the 13-AE-2149 dyke emplaced in an intermediate host metamangerite with a diffuse lower contact, and that displays a weakly peraluminous character (ASI of 1.08, Fig. 13a, Table 2) that is intermediate between the other PGD investigated in this study and those reported by Lentz (1996). This lower peraluminous signature may reflect an interaction of the dyke with its host during its emplacement, as proposed by Lentz (1996) for western Grenvillian granitic pegmatites.

The weak to strong peraluminous character associated with P_2O_5 contents of 0.02-0.40 wt.% (Fig. 13f, Table 2) of the PGD from the Lac Okaopéo region correspond to the peraluminous intermediate phosphorous serie defined by Linnen and Cuney (2005). It contrast with the metaluminous Grenvillian LREE-enriched granitic pegmatites of Lentz (1996) (Fig. 13a) and with REE-enriched granitic pegmatites reported elsewhere that are ascribed to alkaline intrusive (Dill, 2010, 2015; Ercit, 2005; London, 2016). Allanite is a major LREE carrier in granitoids with ASI below 1.2 (Bea, 1996) and in LREE-enriched granitic pegmatites from the abyssal class, usually ascribed to metaluminous to subaluminous compositions (Ercit, 2005; Ford, 1982; Lentz, 1996, 1991), i.e. not in strongly peraluminous melt. In the PGD from the Lac Okaopéo region, allanite is hosted in three metaplutonic hosted PGD, two of them displaying ASI ranging from 1.18 to 1.35 (13-TC-5072 and 13-FS-1202 PGD respectively, Table 2) that are not compatible with the formation of allanite. In contrast, the presence of monazite in paragneisses-hosted PGD with ASI ranging from 1.19 to 1.36 (Table 2) is consistent with its expression as a major and widespread LREE-carrier in a variety of granitoids especially in peraluminous granite and abyssal granitic pegmatites (Bea, 1996; Ercit, 2005; Linnen and Cuney, 2005; Montel, 1993; Rapp and Watson, 1986), but its sole presence as LREE-bearing phase in PGD is shown for the first time in the Grenville Province.

The monazite- and allanite-bearing PGD from the Lac Okaopéo region are generally more concentrated in REE and more fractionated in LREE over HREE than those of the most enriched samples of Lentz (1996), with ΣREE between 1418 to 7048 ppm (monazite-bearing PGD) and between 2393 to 9242 ppm (13-TC-5072 and 13-FS-1202 allanite-bearing PGD), associated with La_N/Yb_N up to 938 (Fig. 13b, Table 2). The ΣREE content of PGD from the Lac Okaopéo region increases with (i) decreasing Eu/Eu* anomaly from 0.72 down to 0.12 (Fig. 13b, Table 2), and (ii) with increasing U and Th contents (Fig. 13c), Th being much more concentrated than U (Th/U ratio between 25 and 74, Table 2). Both features are consistent with the increasing proportion of REE-bearing phases relative to major minerals that represent sinks for Eu (e.g. Bea, 1996; London, 2008). The U and Th contents increase more rapidly with ΣREE in monazite-bearing than in allanite-bearing dykes (Fig. 13c) as marked by the formation of ThO_2-rich monazite relative to allanite (Tables 3-4).

The monazite- and allanite-bearing PGD present unusual and some distinct geochemical trends (Fig. 13). The high Zr/Hf ratio (Fig. 13e) associated with high contents of Zr and Hf (up to 1480 and 41.5 ppm respectively, Table 2) and the very low contents of Nb and Ta of the PGD (Table 2) is characteristic of alkaline melts (Linnen and Cuney, 2005; Linnen and Keppler, 2002; Zaraisky et al., 2009). The quite stable Zr/Hf with increasing ΣREE is also a characteristic feature of alkaline melts in which the high zircon solubility prevents the fractionation of Zr over Hf associated with zircon growth (Ellison and Hess, 1986; Linnen, 1998; Linnen and Cuney, 2005; Linnen and Keppler, 2002; Zaraisky et al., 2009). The contrasting behavior of the Nb/Ta ratio in monazite- and allanite-bearing PGD, with increasing Nb/Ta ratio and ΣREE content in monazite-bearing and decreasing Nb/Ta ratio with increasing ΣREE content in allanite-bearing PGD (Fig. 13e), suggest either distinct (i) magmatic processes, or (ii) fractionation of Nb over Ta associated with distinct sources or (iii) with the crystallization of monazite over allanite. The former hypothesis is unlikely

according to the lack of Nb and Ta minerals in the dykes. Accordingly, the whole-rock geochemistry of the REE-rich PGD from the Lac Okaopéo region display contrasting signatures with (i) major elements characteristics of intermediate phosphorous peraluminous granites (e.g. Linnen and Cuney, 2005), and (ii) trace elements (Zr-Hf-Nb-Ta and the REE) enrichment and fractionation more akin to a peralkaline signature of the melts (e.g. Ellison and Hess, 1986; Linnen, 1998; Linnen and Cuney, 2005; Linnen and Keppler, 2002; Zaraisky et al., 2009).

8.4. LREE-rich PGD from the Lac Okapéo region in the granitic pegmatite classification scheme

The PGD from the Lac Okaopéo region display peraluminous signatures (Fig. 13a, Table 1), are LREE enriched (Fig. 13b) and are composed of a quartz+K-feldspar+plagioclase+biotite (for major minerals, Figs. 8a, d, 11a-c) with either monazite or allanite and ubiquitous zircon (Figs. 8a-c, 11b-f). Mineralized granitic pegmatites displaying a peraluminous signature usually belong to the LCT family (Černý et al., 2012; Černý and Ercit, 2005; Ercit, 2005; London, 2005, 2008; Martin and De Vito, 2005). Even though the seven PGD described in this paper are peraluminous, they do not share any other characteristic of this family since none of them contain any muscovite, nor Li-, Cs- or Ta-minerals, nor tourmaline or beryl and are not enriched in Rb, Ga or Sn. In addition, their trace elements geochemistry is more akin to alkaline melts (e.g. Linnen and Cuney, 2005; Linnen and Keppler, 2002). In the classical classification scheme, the NYF family contains pegmatitic bodies derived from alkaline intrusive bodies and are enriched in Nb, Y, F, Be, Ti, Sc, Zr with LREE concentrations up to 100 to 800 times chondritic and little depletion in HREE (Černý et al., 2012; Černý and Ercit, 2005; Ercit, 2005; London, 2005, 2008). PGD investigated from the Lac Okaopéo region do not contain any minerals hosting the usual rare-metals of the NYF family, show an LREE enrichment from over 1,000 to almost 10,000 times the chondritic

776 value (Fig. 13b), a strong depletion of HREE and, for six of them (exception is the 13-AE-
777 2149 PGD) are most probably derived by partial melting of a deeper-seated metasedimentary
778 source. Therefore, they are not characteristic of the NYF family neither.

779 Ercit (2005) reviewed the general characteristics of world-wide REE-enriched granitic
780 pegmatites. These are mainly observed in Colorado, Virginia and Northern Carolina (USA),
781 Kola-Karelia and Pribaikal regions, and Aldan Shield (Russia), southern Japan, Antsirabé-
782 Kitsamby and Ankazobe districts (Madagascar), and finally in the SW Grenville Province,
783 that represents one of the major districts of such REE occurrences (e.g. Ford, 1982; Lentz,
784 1996, 1991). Ercit (2005) emphasized that REE-enriched granitic pegmatites do not always
785 fall in fields of the previously described granitic pegmatites families (either LCT or NYF) of
786 Černý (1991). However, in the abyssal class, two main types of REE-enriched granitic
787 pegmatites are common: (i) the LREE-enriched that typically host REE as an allanite-
788 monazite and/or uraninite assemblage, and (ii) the (Y,HREE)-enriched that typically host
789 REE assemblage as more complex rare-element assemblages than the previous one (Ercit,
790 2005). The PGD from the Lac Okaopéo region display ΣLREE contents between 1407 and
791 7435 ppm hosted in either monazite or allanite (Figs. 6f, 7b-d, g, 8a-c, 9-12) and ΣHREE
792 contents between 11 and 485 ppm (Fig. 13b, Table 2) and can therefore be ascribed to the
793 LREE-enriched type of Ercit (2005).

794 According to previous sections of the discussion, the zoned PGD from the Lac
795 Okaopéo region intruded metamorphosed sedimentary units and metaigneous complexes in a
796 post-tectonic setting relative to the structure and metamorphism of their host rocks with no
797 link, for six of them (except for the 13-AE-2149 PGD), to a plutonic body (see sections 8.1.
798 and 8.2.) and therefore correspond to the class of ‘pseudopegmatites’ proposed by Dill (2016)
799 in its CMS (Chemical composition - Mineral assemblage - Structural geology) classification
800 scheme. The 13-AE-2149 PGD however could derive by differentiation of a late-Ottawan

plutonic suite and would therefore correspond to the 'pegmatite' class of Dill (2016). In addition, according to the same scheme the monazite-bearing PGD are paragneisses-hosted zoned meter-sized (Zr)-LREE quartz-feldspar-biotite pseudopegmatite (monazite), whereas the 13-TC-5072 and the 13-FS-1202 allanite-bearing PGD are metamonzogranite-hosted zoned decimeter- to meter-sized (Zr)-LREE quartz-feldspar-biotite pseudopegmatite (allanite) and quartz metamonzodiorite-hosted zoned decimeter- to meter-sized (Zr)-LREE quartz-feldspar-biotite pseudopegmatite (allanite), respectively. In the same way and according to the its possible derivation from a plutonic source, the 13-AE-2149 allanite-bearing PGD is a metamangerite-hosted zoned centimeter- to meter-sized (Zr)-LREE quartz-feldspar-biotite (pseudo)pegmatite (allanite) according to Dill (2016).

Conclusions

The seven pegmatitic granite dykes (PGD) from the Lac Okaopéo region described in this paper represent new LREE-only occurrences in the central Grenville Province. They intrude paragneisses from the Plus-Value Complex or felsic to intermediate metaplutonic complexes from the Bardoux and Castoréum Plutonic Suites that are part of the Allochthonous Belt of the Grenville Province. These LREE occurrences are undeformed dykes discordant to the foliation of their host rocks with no evidence for interconnection with leucosomes and are thus considered as post-tectonic relative to the structure and metamorphism of their host rocks that recorded the Ottawan orogenic phase. Their peraluminous signature, high Nb/Ta ratio and high fractionation of LREE over HREE suggest their derivation by partial melting of metasedimentary units, either belonging to the base of the Allochthonous or to the Parautochthonous Belt. U-Pb dating of magmatic monazite from two of the LREE occurrences yield concordant igneous ages at 996.7±5.3 Ma and 1005.4±4.4 Ma that correspond to an emplacement at the initiation of the Rigolet orogenic phase considered to represent a short-lived phase of renewed crustal thickening as recorded by

826 deformation and metamorphism of the Parautochthonous Belt between ca. 1005 and 980 Ma.
827 Further isotopic and geochronological investigations are needed to constrain their derivation
828 either from the Allochthonous or the Parautochthonous Belt.

829 Field relationships show that monazite host the LREE-mineralization for PGD hosted
830 by paragneisses of the Plus-Value Complex, and that allanite host the LREE-mineralization
831 for PGD hosted by metagranitoids of the Bardoux and Castoréum Plutonic Suites, in both
832 cases without complementary rare-metals minerals. The geochemistry and rare-metals
833 assemblage do not allow to ascribe these PGD to the classical LCT and NYF family. In
834 addition, even if a peraluminous character is marked by the major elements whole-rock
835 geochemistry, the Zr/Hf ratio associated with high Zr and Hf contents, the very low contents
836 in Nb and Ta and the very high contents in LREE are more akin to a peralkaline series.

837 The peraluminous signature of the mineralized PGD contrasts with the typical
838 metaluminous to subaluminous signature of REE-enriched granitic pegmatites reported
839 elsewhere. This peraluminous composition is consistent with the crystallization of monazite-
840 (Ce) but is at odd with the presence of allanite-(Ce). This contribution constitutes the first
841 evidence in the Grenville Province of such a monazite-only mineralization hosted in PGD.
842 Further investigations are required to identify the factors controlling the crystallization of
843 allanite in some of these PGD.

Appendix A: Detailed mapping of the monazite-bearing pegmatitic granite outcrops

9. 13-AM-07 monazite-bearing pegmatitic granite dyke (PGD)

The 13-AM-07 monazite-bearing pegmatitic granite dyke (PGD) and REE occurrence is located in the north of the 22K/10 NTS sheet (Fig. 3) and is exposed as a small (a few square meters in surface) and flat lying outcrop (Fig. A-2a). The detailed map of this outcrop is available in the Fig. A-1.

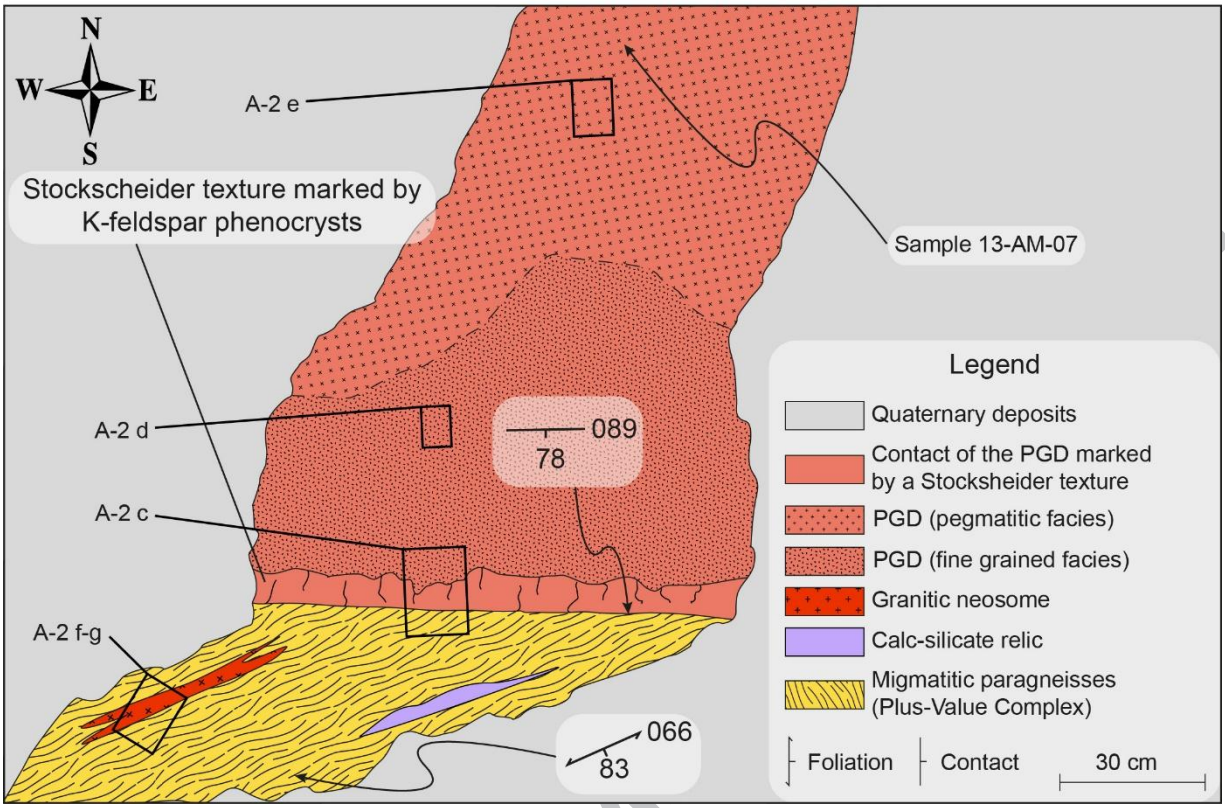

Figure A-1: Detailed map of the 13-AM-07 outcrop made of migmatitic paragneisses from the Plus-Value Complex intruded by a discordant REE-rich pegmatitic granite dyke. Abbreviation: PGD = pegmatitic granite dyke.

The PGD is steep-dipping and discordant to the foliation of the Plus-Value Complex migmatitic paragneisses (Figs. A-2b-c, 5a). The dyke is whitish (Figs. A-2b-e) and is layered parallel to the contact. The discordant contact with the paragneisses is marked by the development of a Stockscheider texture visible in the development of K-feldspar phenocrysts reaching a length of up to 5 cm (Fig. A-2c). From the contact and towards the core of the dyke, these phenocrysts are in contact with a 20 to 50 cm wide fine-grained facies (Figs. A-2b and d) grading onto a pegmatitic facies (Figs. A-2b and e) with crystals reaching up to ca. 3 cm in the center of the dyke.

The host paragneisses from the Plus-Value Complex are migmatitic with granitic±garnet-biotite leucosomes that can reach several tens of centimeters in width (Figs. A-2b, f-g).

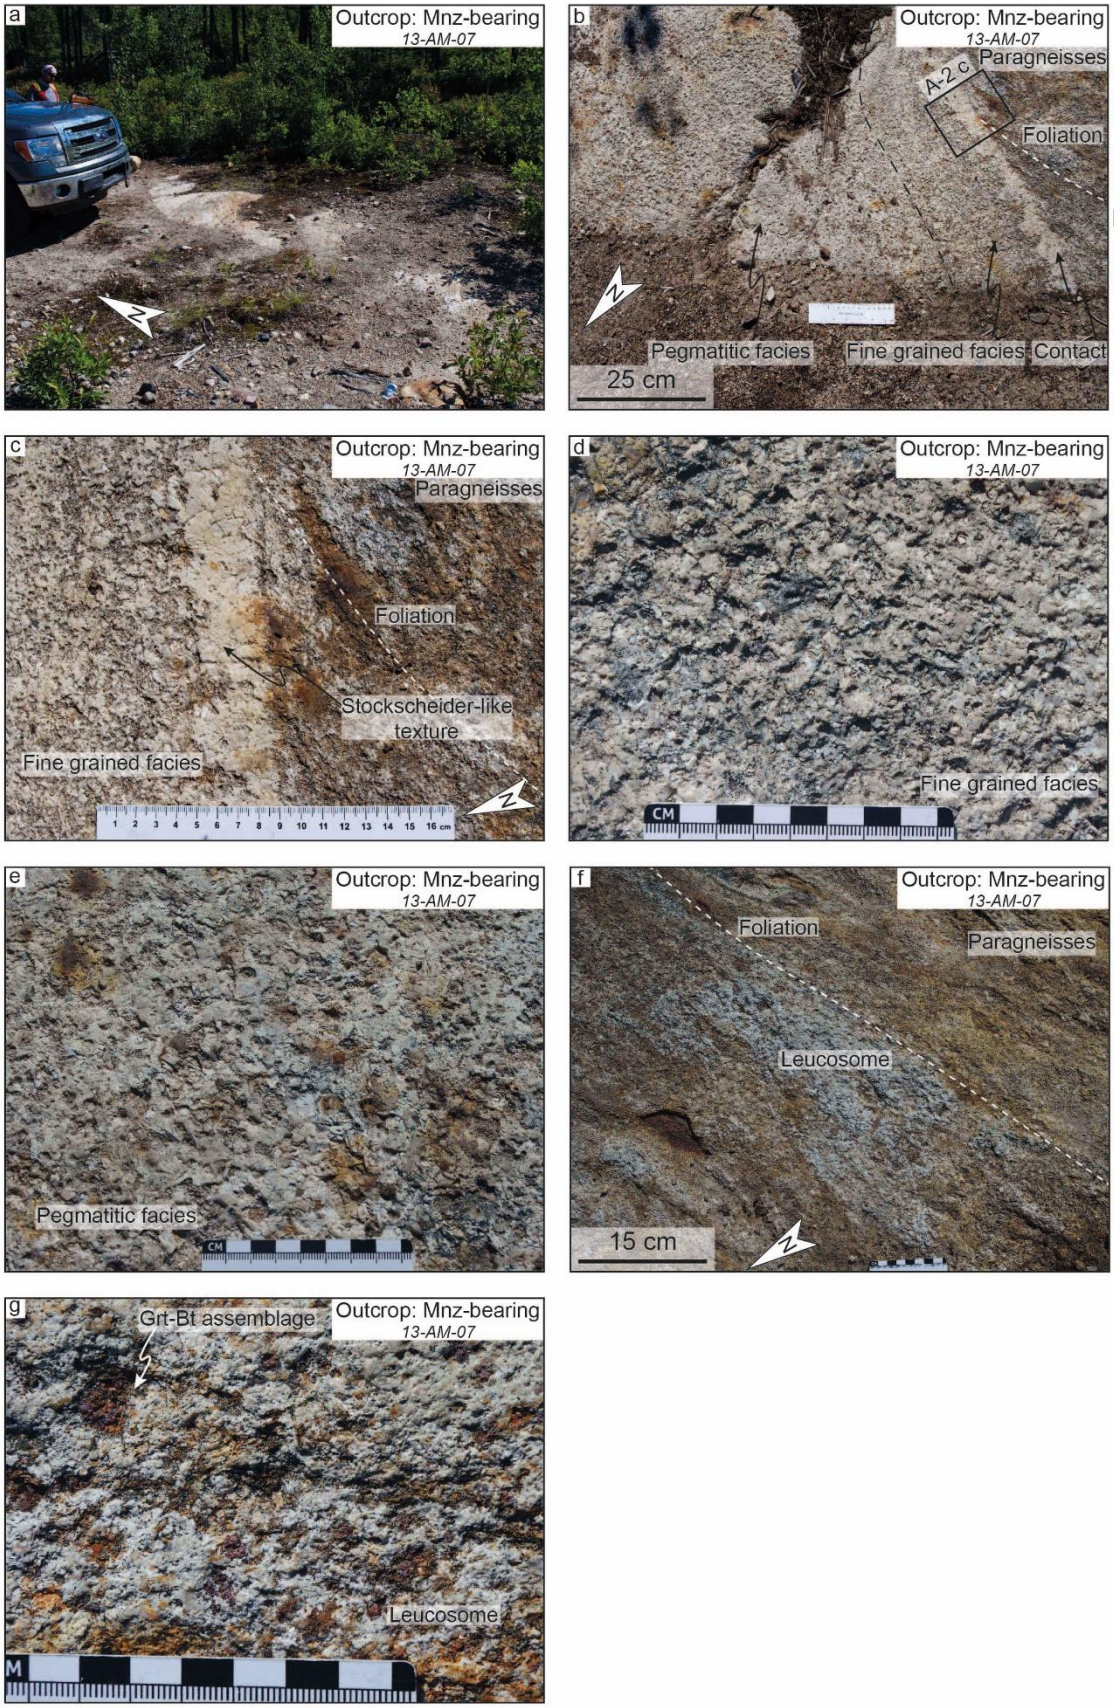

Figure A-2: **Photographs of the 13-AM-07 outcrop from the Lac Okaopéo region. a: general view of the 13-AM-07 outcrop composed of a pegmatitic granite dyke intruding paragneisses from the Plus-Value Complex; b: large view of the relationships between the dyke and the paragneisses. Note the discordant contact as evidenced by the crosscut foliation of the paragneisses by the dyke; c: detailed view of Stockscheider-like contact between the pegmatitic granite dyke and the intruded paragneisses marked by the crystallization of**

feldspar from the dyke perpendicular to the contact; d: detailed view of the fine grained facies dominated by feldspar and quartz; e: detailed view of the pegmatitic facies dominated by feldspar and quartz; f: typical facies of the Plus-Value Complex paragneisses showing the importance of leucosomes in this facies; g: mineralogy of the leucosomes from the migmatitic Plus-Value Complex paragneisses. Note the domination of quartz-feldspar in this granitic leucosome, the abundance of the garnet-biotite assemblage expressed as several millimeters crystals and the lack of deformation in these leucosomes. Abbreviations: Bt = biotite; Grt = garnet; Mnz-bearing = monazite-bearing pegmatitic granite dyke.

10. 13-AM-10 monazite-bearing PGD

The 13-AM-10 monazite-bearing PGD and REE occurrence is located at the south of the 13-AM-07 outcrop, in the north of the 22K/10 NTS sheet (Fig. 3), and is exposed as a steep-dipping outcrop along a gravel road (Fig. A-4a). The detailed map of this outcrop is available in Fig. A-3.

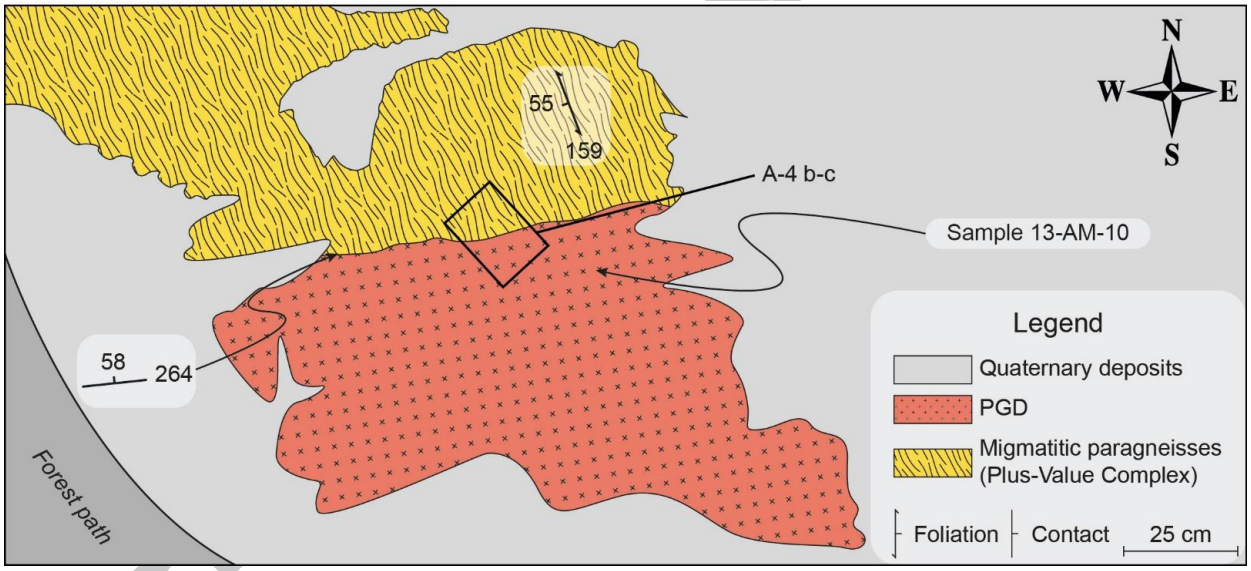

Figure A-3: Detailed map of the 13-AM-10 outcrop made of migmatitic paragneisses from the Plus-Value Complex intruded by a discordant REE-rich pegmatitic granite dyke. Abbreviation: PGD = pegmatitic granite dyke.

The PGD is steep-dipping and discordant to the rusty Plus-Value Complex migmatitic paragneisses (Figs. A-4c, 5a). The contact between the dyke and the host paragneiss is straight but is slightly diffuse (over a few millimeters, Fig. A-4b) and the dyke do not display noticeable facies variations.

11. 13-AM-13 monazite-bearing PGD

The whitish 10 to 20 meters wide 13-AM-13 monazite-bearing PGD and REE occurrence is located to the south of the 13-AM-10 outcrop, in the north of the 22K/10 NTS sheet (Fig. 3), and is exposed as a large flat lying outcrop (Fig. A-6a). The Fig. A-5 proposes the detailed mapping of this outcrop with localization of the samples and of the photographs presented in Fig. A-6.

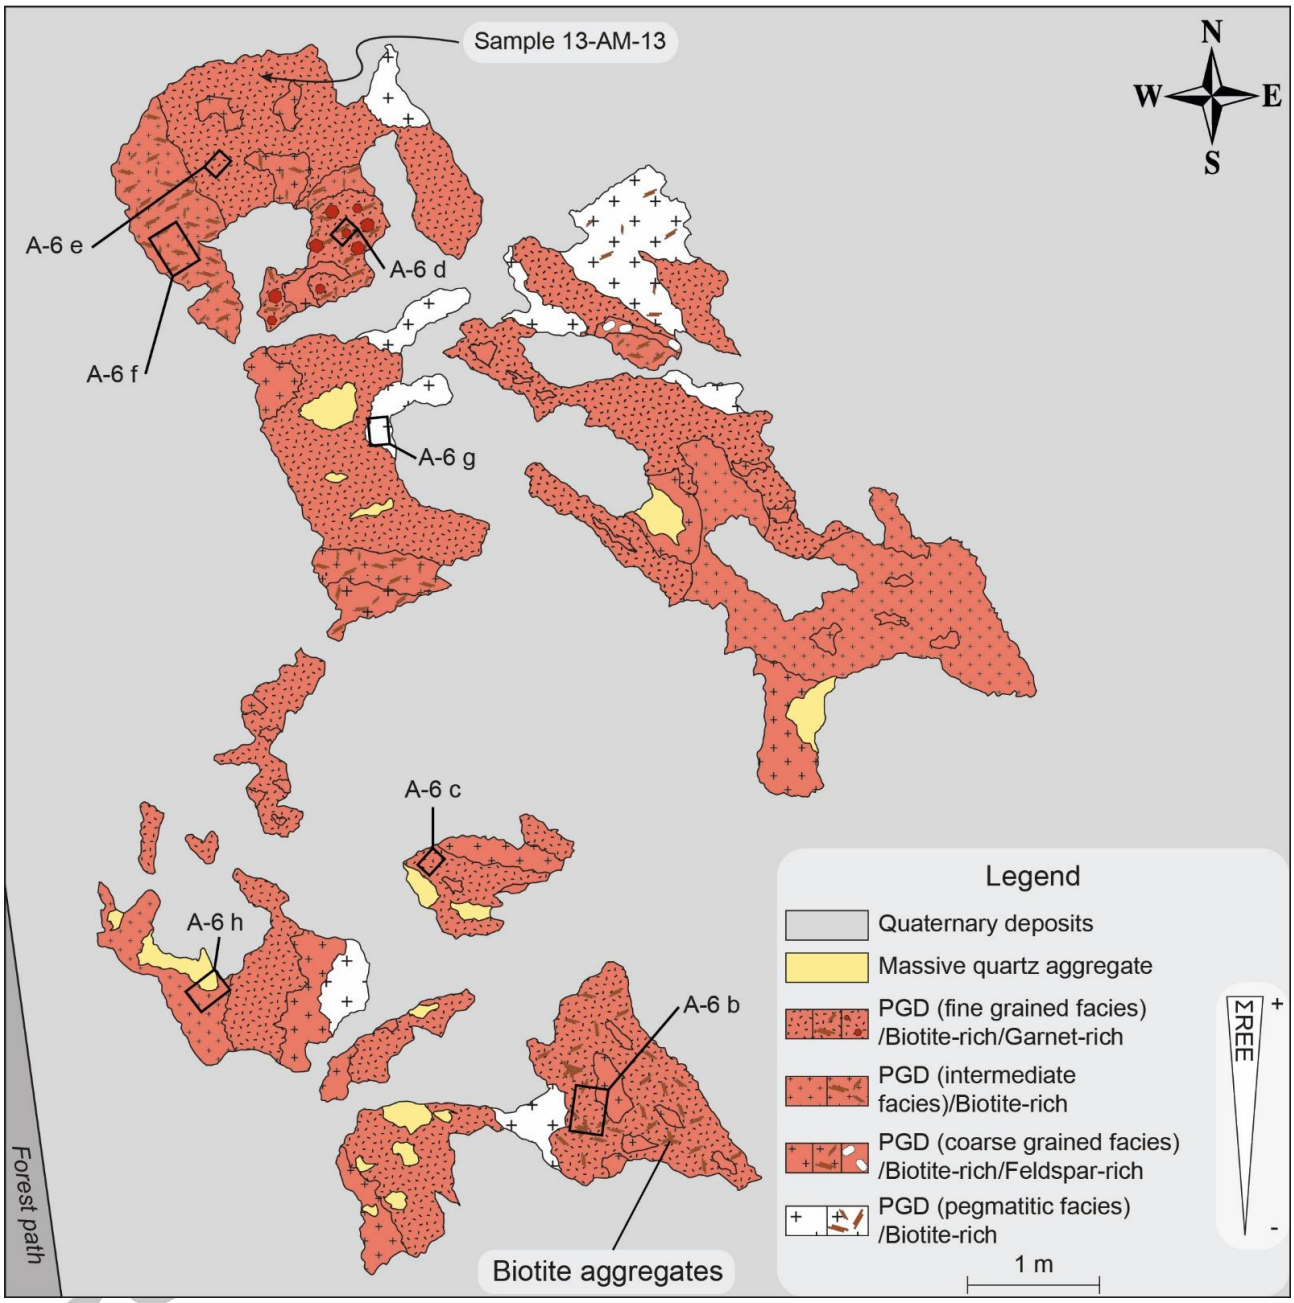

Figure A-5: Detailed map of the 13-AM-13 outcrop made of migmatitic paragneisses from the Plus-Value Complex intruded by a discordant REE-rich pegmatitic granite dyke. Abbreviation: PGD = pegmatitic granite dyke.

The PGD is steep-dipping and discordant to the foliation of the paragneisses from the Plus-Value Complex (Fig. 5a). The contact between the PGD and the host paragneisses is poorly exposed but the distribution of outcrops suggests that the contact is not straight over several meters.

The PGD is dominated by a fine-grained (1 mm to sometimes over 1 cm) quartz and feldspar-rich facies with minor biotite and garnet (Figs. A-5 and 6b-d). This facies is the main host for the mineralization expressed as sub-euhedral monazite grains (Fig. A-6e). The PGD comprises randomly distributed tens of centimeters to 1 m large patchy zones characterized by (i) an intermediate quartz and feldspar-rich±biotite facies (Figs. A-5, A-6f), (ii) a coarse-grained quartz and feldspar-rich facies with more or less abundant biotite and phenocrysts of feldspar (Fig. A-6b), and (iii) a pegmatitic quartz and feldspar-rich±biotite facies (some grains over 5 cm, Fig. A-6g). Locally, up to ca. 20 cm centimeters wide quartz aggregates are also noticeable but do not seem associated with any of the previous facies (Figs. A-5 and 6h). The transition between two facies is mostly diffuse and difficult to delineate, but it may also be underlined by biotite aggregates (Fig. A-6b).

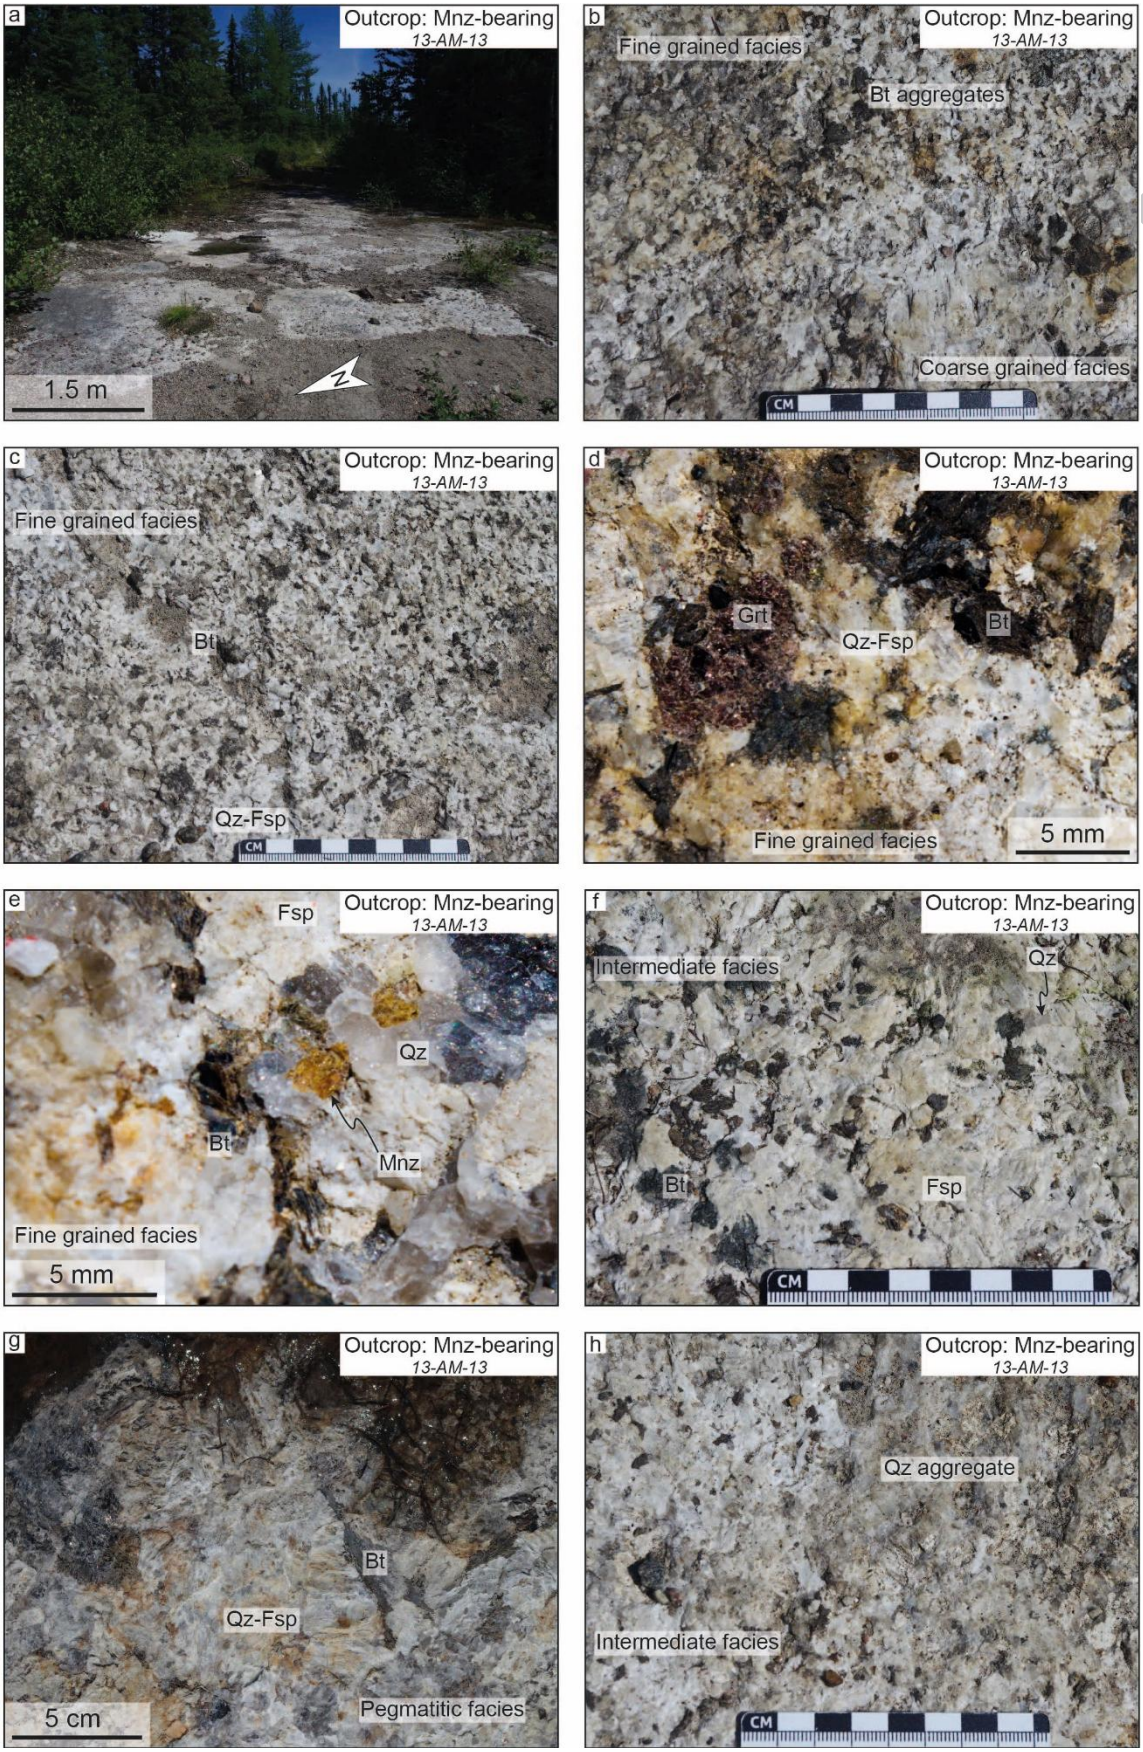

Figure A-6: Photographs of the 13-AM-13 outcrop from the Lac Okaopéo region. a: general view of the 13-AM-13 outcrop composed of a pegmatitic granite intruding paragneisses from the Plus-Value Complex; b: typical transition between the fine and coarse grained facies underlined by biotite aggregates. Note that the

abundance of biotite in the fine grained facies on this photograph is related to the vicinity of the coarse grained facies; c: typical fine grained facies dominated by a quartz+feldspar±biotite assemblage; d: detailed view of a garnet phenocryst in the fine grained facies; e: monazite crystals from the fine grained facies; f: typical intermediate facies composed of a quartz-feldspar-biotite assemblage; g: typical pegmatitic facies essentially composed of a quartz-feldspar-biotite assemblage in which feldspar and biotite crystals can reach over 5 cm; h: quartz aggregates in the intermediate facies. Abbreviations: Bt = biotite; Fsp = feldspar; Grt = garnet; Mnz = monazite; Mnz-bearing = monazite-bearing pegmatitic granite dyke; Qz = quartz.

12. 13-TC-5008 monazite-bearing PGD

The 13-TC-5008 monazite-bearing PGD and REE occurrence is located in the north of the 22K/07 NTS sheet (Fig. 3) and is exposed as a large flat lying outcrop (Fig. A-8a). The Fig. A-7 proposes the detailed mapping of this outcrop with localization of the samples and of the photographs presented in Fig. A-8.

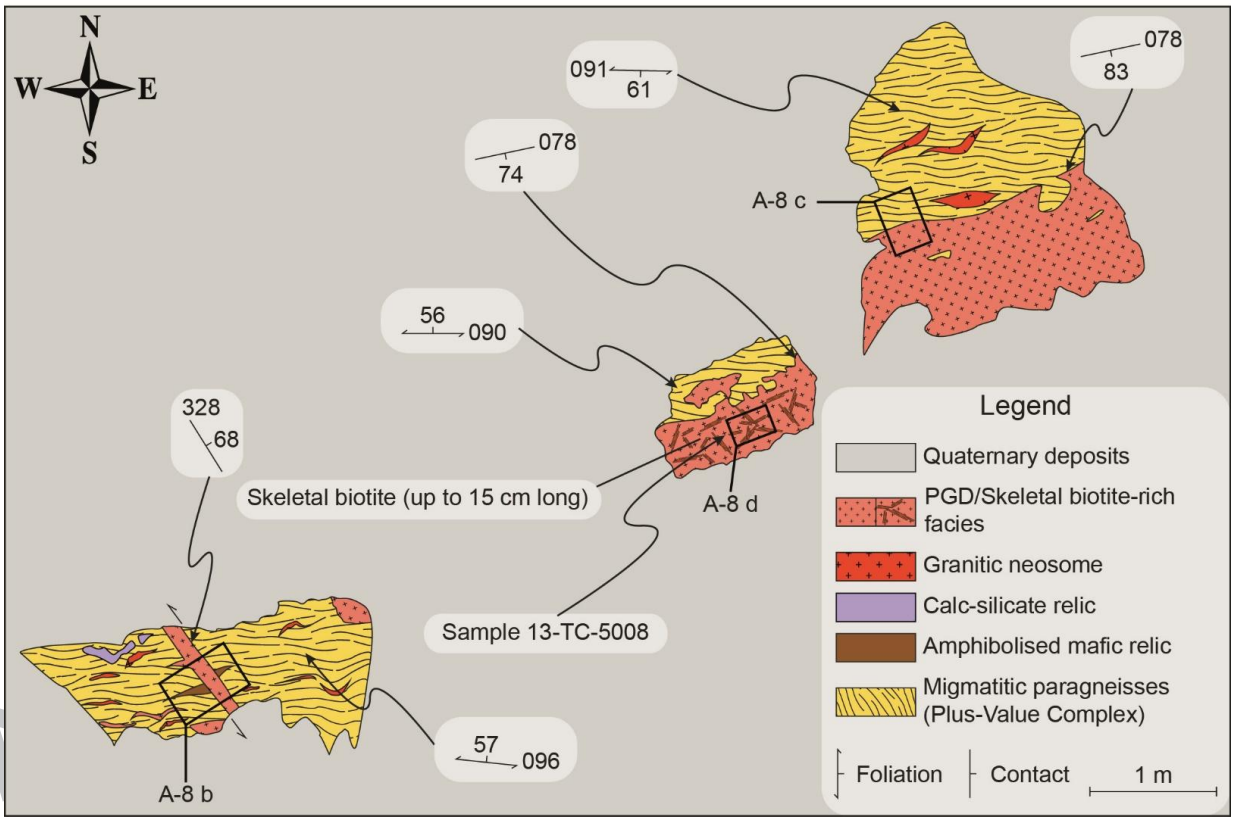

Figure A-7: Detailed map of the 13-TC-5008 outcrop made of migmatitic paragneisses from the Plus-Value Complex intruded by a discordant REE-rich pegmatitic granite dyke. Abbreviation: PGD = pegmatitic granite dyke.

The 13-TC-5008 outcrop displays several showings of a few square meters large area (Figs. A-7, A-8a) made of large or thin (ca. 10 cm wide, Fig. A-8b) steep-dipping PGD discordant to the foliation of the migmatitic paragneisses of the Plus-Value Complex (Figs. A-

8b, 5a). The contact is locally diffuse (over a few millimeters) and is either straight or wavy (Figs. A-8b-c). It seems to represent a zone of reactions between the granitic melt and the intruded metasediments as it may be underlined in the PGD by garnet-biotite aggregates (Fig. A-8c).

The few square meters PGD showings and the thin whitish PG dyke do not display any zoning from the contact to their core. However, some patchy zoning made of facies enriched in skeletal biotite (cluster as arborescent arrangements of up to 15 cm biotite crystals, Fig. A-8d) are noticeable and are about a few tens of centimeters wide. The transition between these patches and the dominant facies is diffuse.

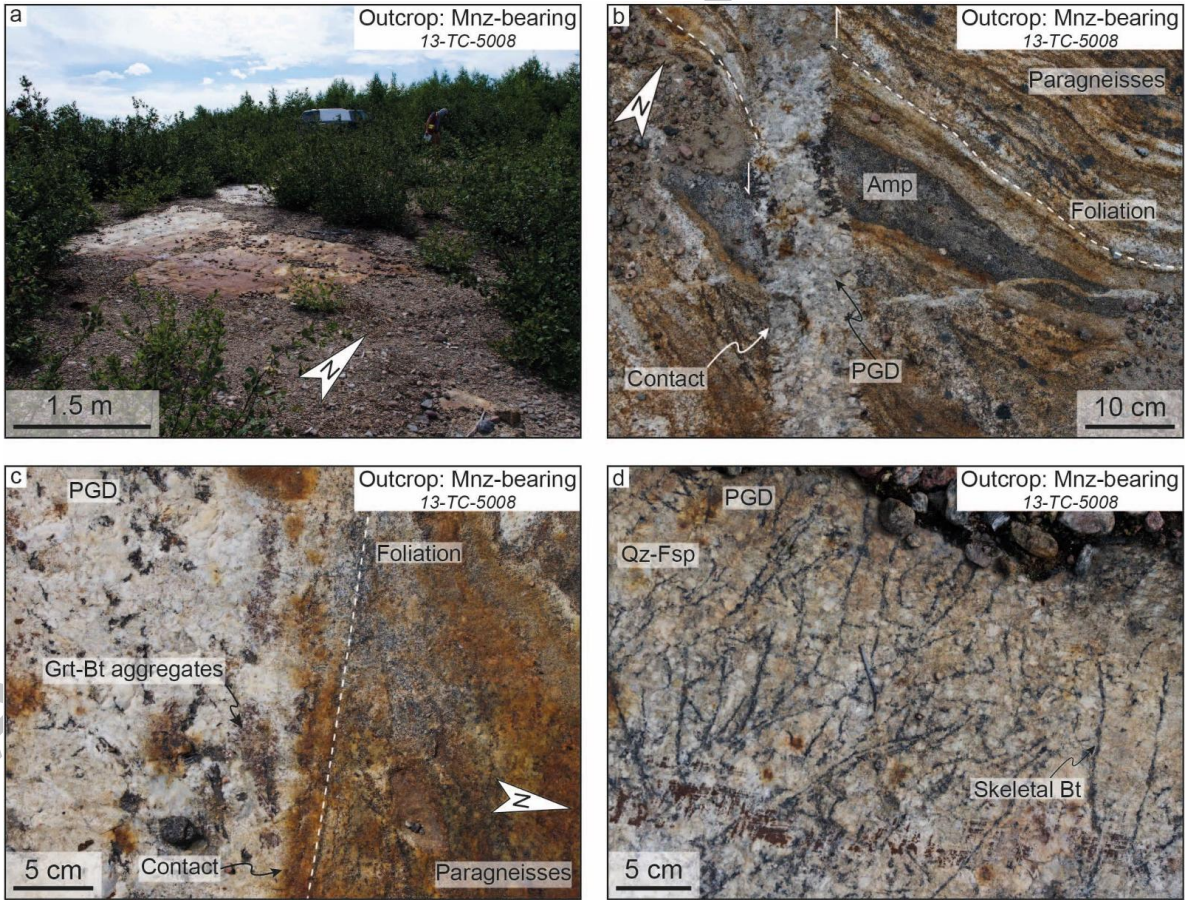

Figure A-8: Photographs of the 13-TC-5008 outcrop from the Lac Okaopéo region. a: general view of the 13-TC-5008 outcrop composed of a pegmatitic granite intruding paragneisses from the Plus-Value Complex; b: intrusion of a pegmatitic granitic dyke favored by a sinistral shearing that affect both the migmatitic paragneisses from the Plus-Value Complex and the amphibolized mafic relic it contains. The resulting contact is discordant as evidenced by the crosscut foliation of the intruded paragneisses by the dyke; c: locally diffuse contact between the dyke and the intruded paragneisses delineated by garnet-biotite aggregates; d: arborescent textures made by skeletal crystals reaching up to 15 cm long. Abbreviations: Amp = amphibolized

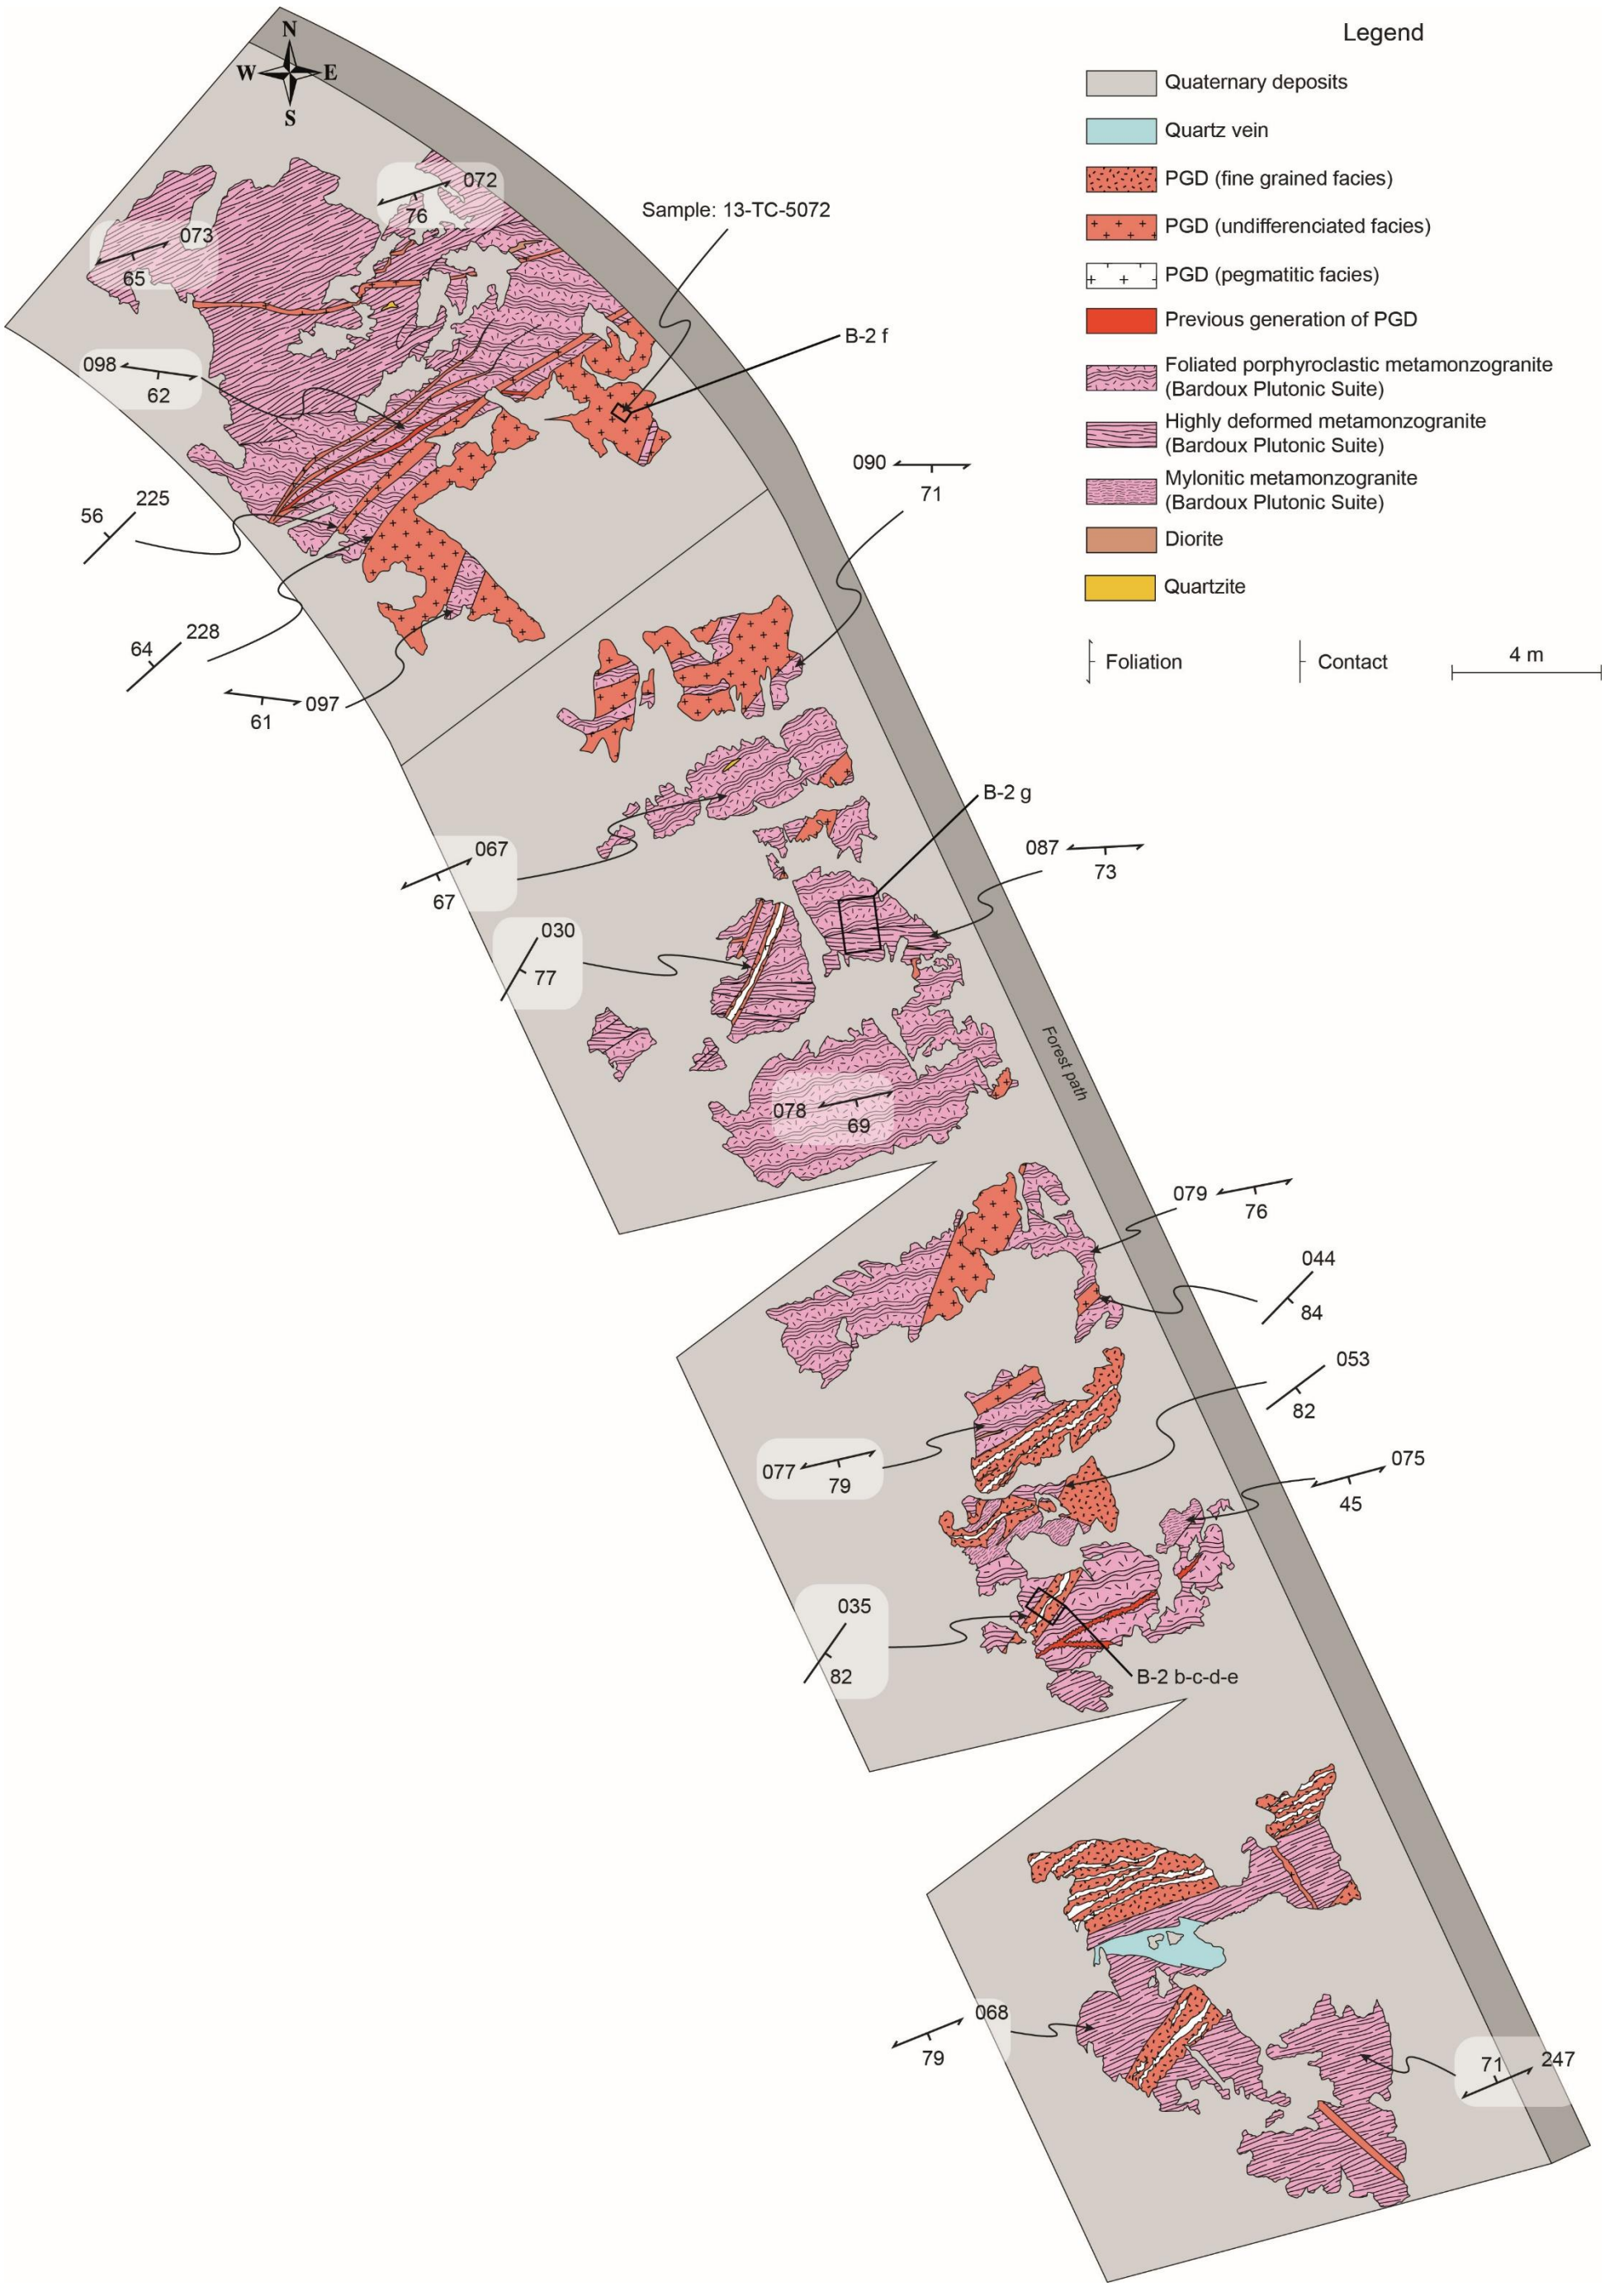
Appendix B: Detailed mapping of the allanite-bearing pegmatitic granite outcrops

13. 13-TC-5072 allanite-bearing pegmatitic granite dyke (PGD)

The 13-TC-5072 allanite-bearing pegmatitic granite dyke (PGD) and REE occurrence is located in the south of the 22K/10 NTS sheet (Fig. 3) and is exposed as a large and dome shaped outcrop (Fig. B-2a). The detailed map of this outcrop is available in the Fig. B-1. It consists in numerous straight pinkish (fresh color) PGD (up to 4 m wide, Figs. B-1 and B-2b-f) intruding a metamonzogranite from the Bardoux Plutonic Suite.



<u>Figure B-1:</u> Detailed map of the 13-TC-5072 outcrop made of a metamonzogranite from the Bardoux Plutonic Suite intruded by discordant REE-rich pegmatitic granite dykes. Abbreviation: PGD = pegmatitic granite dyke.

The dykes are steep-dipping and mostly discordant to the fabric of the host metamonzogranite but are locally sub-concordant (Figs. B-2b-c and e, 5b). Several of these dykes may present internal zoning which typically consists in (i) a thin contact (few millimeter to a centimeter wide, zone 1, Figs. B-2b-c), followed by (ii) a ca. 20 to 30 cm wide fine grained facies (ca. < 1 mm and 2 mm, zone 2, Figs. B-2b-c), and (iii) by a coarser grain size zone (ca. 1 to 5 mm, zone 3, Figs. B-2b and d). The (iv) core of the dykes (zone 4, Figs. B-2b and d) may vary from a few centimeters to tens of centimeters wide and displays a pegmatitic texture. It is followed by (v) another fine grained facies (zone 5, Figs. B-2b, B-2d-e), which transition is quite diffuse from the later one, that ends at the boundary of the dyke by (vi) the growth of K-feldspar phenocrysts perpendicular to the contact (zone 6, Figs. B-2b and e). The whole contact is not marked by these phenocrysts that also developed in the fine grained facies with no relations with the dyke boundary (Fig. B-2e), suggesting that it does not correspond to Stockscheider textures. This kind of internal zoning in the dykes of this outcrop is quite representative as most of them display either this sequence or its repetition, probably related to several magmatic pulses. A few intrusive bodies, mostly wider than the dykes, do not display any evident zoning. Allanite grains (Fig. B-2f) are present in both zoned and unzoned intrusive bodies, and seems mostly associated with fine to medium grained facies.

The intruded metamonzogranite from the Bardoux Plutonic Suite displays various textures related to the degree of deformation it underwent, from a foliated facies with rounded rapakivi K-feldspar porphyroclasts to a mylonitic texture with elongated K-feldspar porphyroclasts (Fig. B-2g).

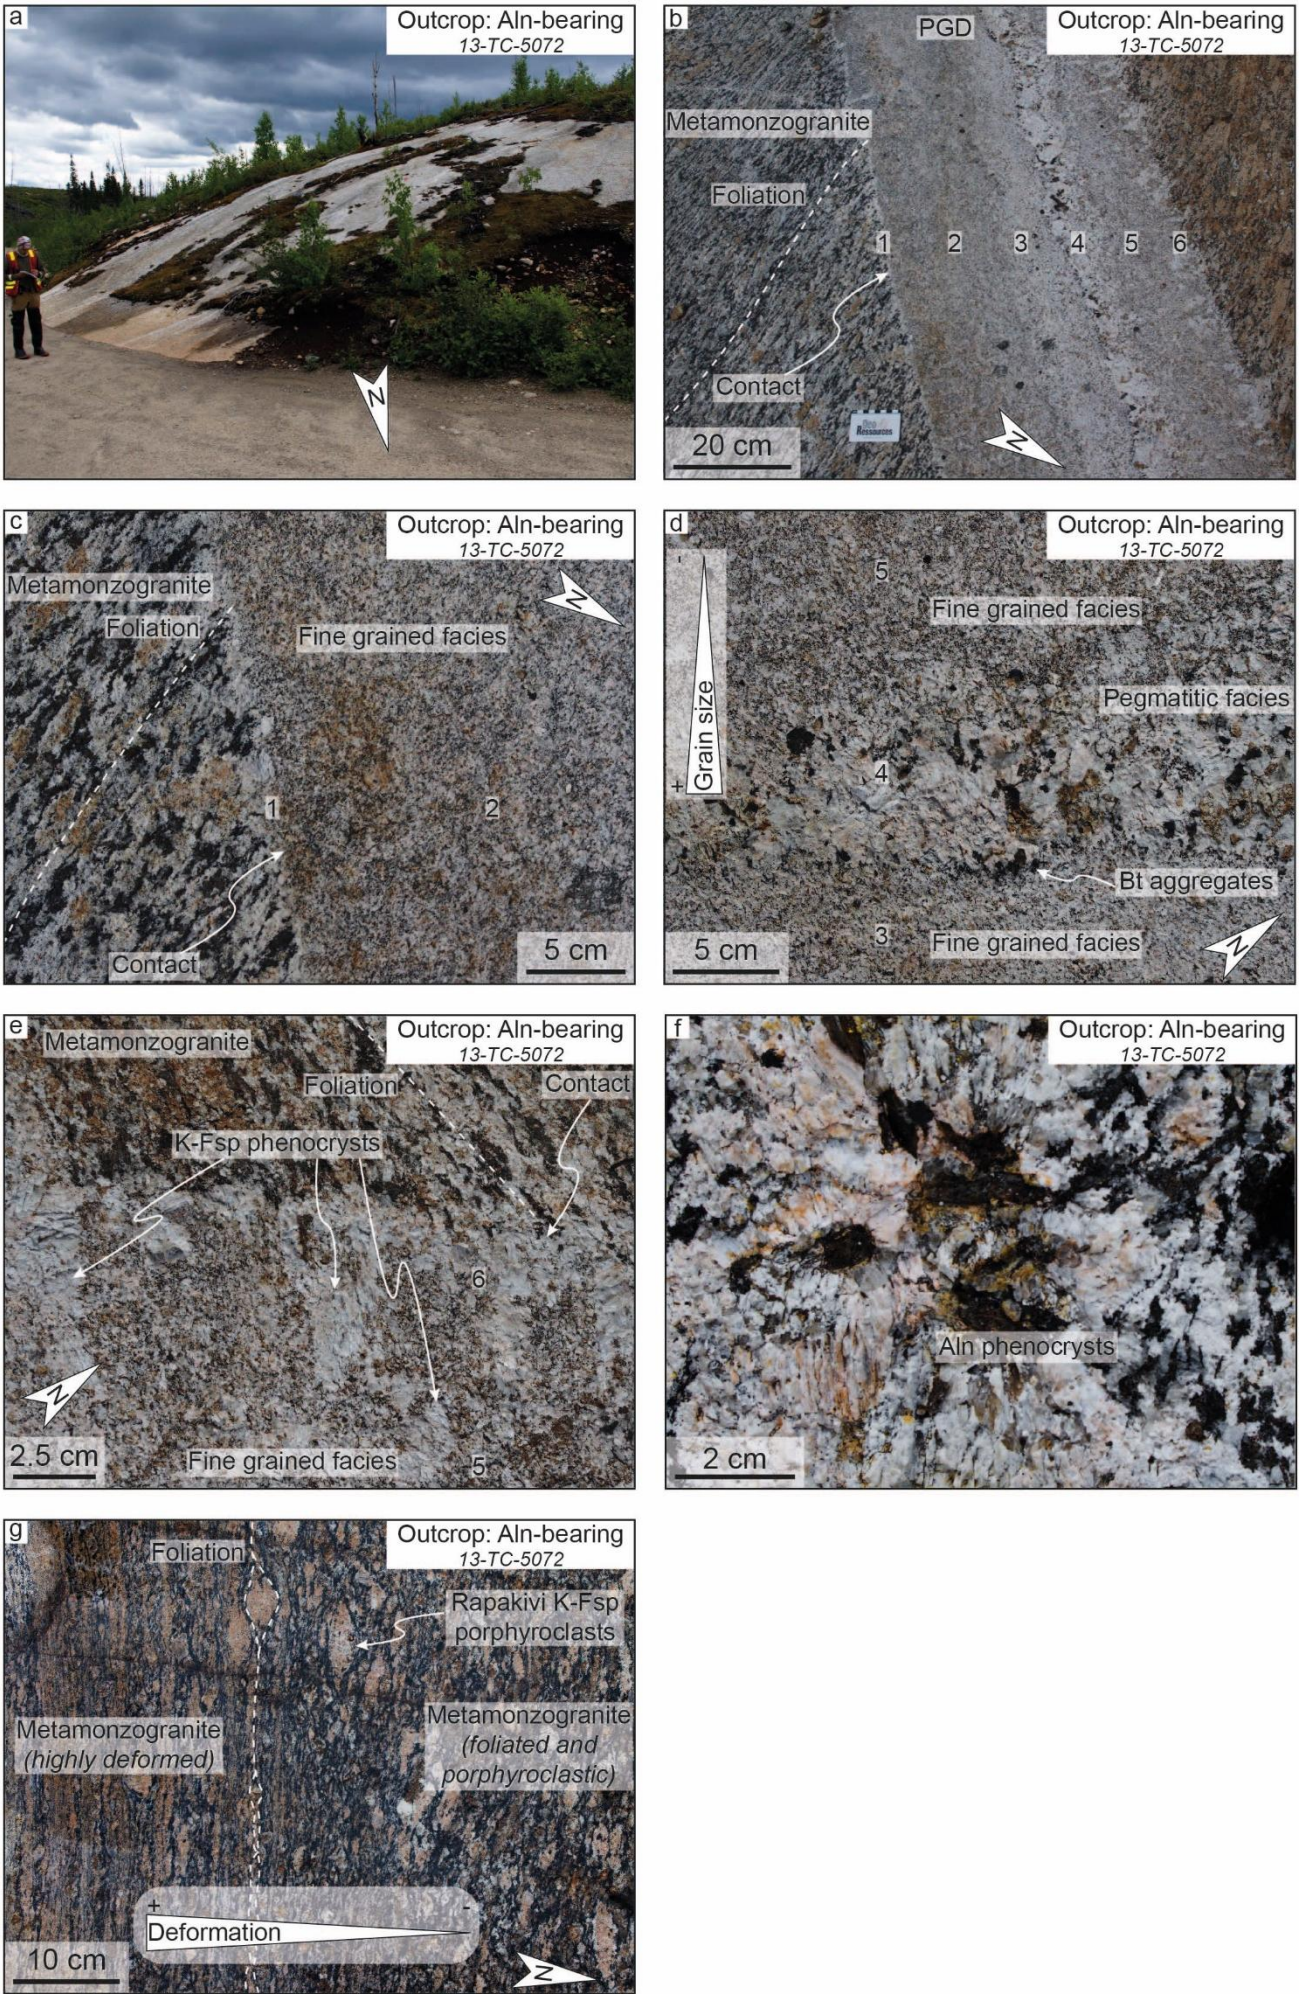


Figure B-2: **Photographs of the 13-TC-5072 outcrop from the Lac Okaopéo region. a: general view of the 13-TC-5072 outcrop composed of a pegmatitic granite intruding as a dyke swarm a metamonzogranite from the Bardoux Plutonic Suite; b: typical dyke zonation of the 13-TC-5072 pegmatitic dykes, with a southeastern boundary (1) marked by a thin zone of reaction with the host rock developed over a few millimeters with almost no biotite, followed by a fine grained facies with increasing grain size and proportions of biotite (2, 3) up to a pegmatitic core (4). This core is followed by a progressive fine grained facies with decreasing grain size zone (5). The northern contact (6) is marked by the development of K-feldspar phenocrysts perpendicular to the contact. Note that the dyke is discordant to the foliation of the intruded metamonzogranite; c: detailed view of the southern contact presented in figure b. Numbers refer to the zones identified in figure b; d: detailed view of the pegmatitic core of the dyke presented in figure b. Note the pegmatitic facies is underlined on its southern boundary by biotite aggregates whereas the northern one is opened to a fine grained facies which transition is undulating along the core. Numbers refer to the zones identified in figure b; e: detailed view of the northern contact presented in figure b. Note the diffuse boundary and the crystallization of K-feldspar phenocrysts perpendicular to the contact. Numbers refer to the zones identified in figure b; f: typical allanite phenocrysts in pegmatitic granite dykes intruding the metamonzogranite; g: typical metamonzogranite facies variations from a foliated and porphyroclastic facies where porphyroclasts of rapakivi K-feldspar are wrapped by the foliation (north) to transposed in a highly deformed facies (south). Abbreviations: Aln = allanite; Aln-bearing = allanite-bearing pegmatitic granite dyke; Bt = biotite; K-Fsp = K-feldspar; PGD = pegmatitic granite dyke.**

14. 13-FS-1202 allanite-bearing PGD

The 13-FS-1202 allanite-bearing PGD and REE occurrence is located at the south of the 13-TC-5072 PGD, in the south of the 22K/10 NTS sheet (Fig. 3), and is exposed as a large (several tens square meters in surface) and flat lying outcrop (Fig. B-4a). The detailed map of this outcrop is available in the Fig. B-3. It consists in numerous straight pinkish (fresh color) PGD (2-5 m wide, Figs. B-3 and B-4b) intruding a quartz metamonzodiorite from the Castoréum Plutonic Suite.

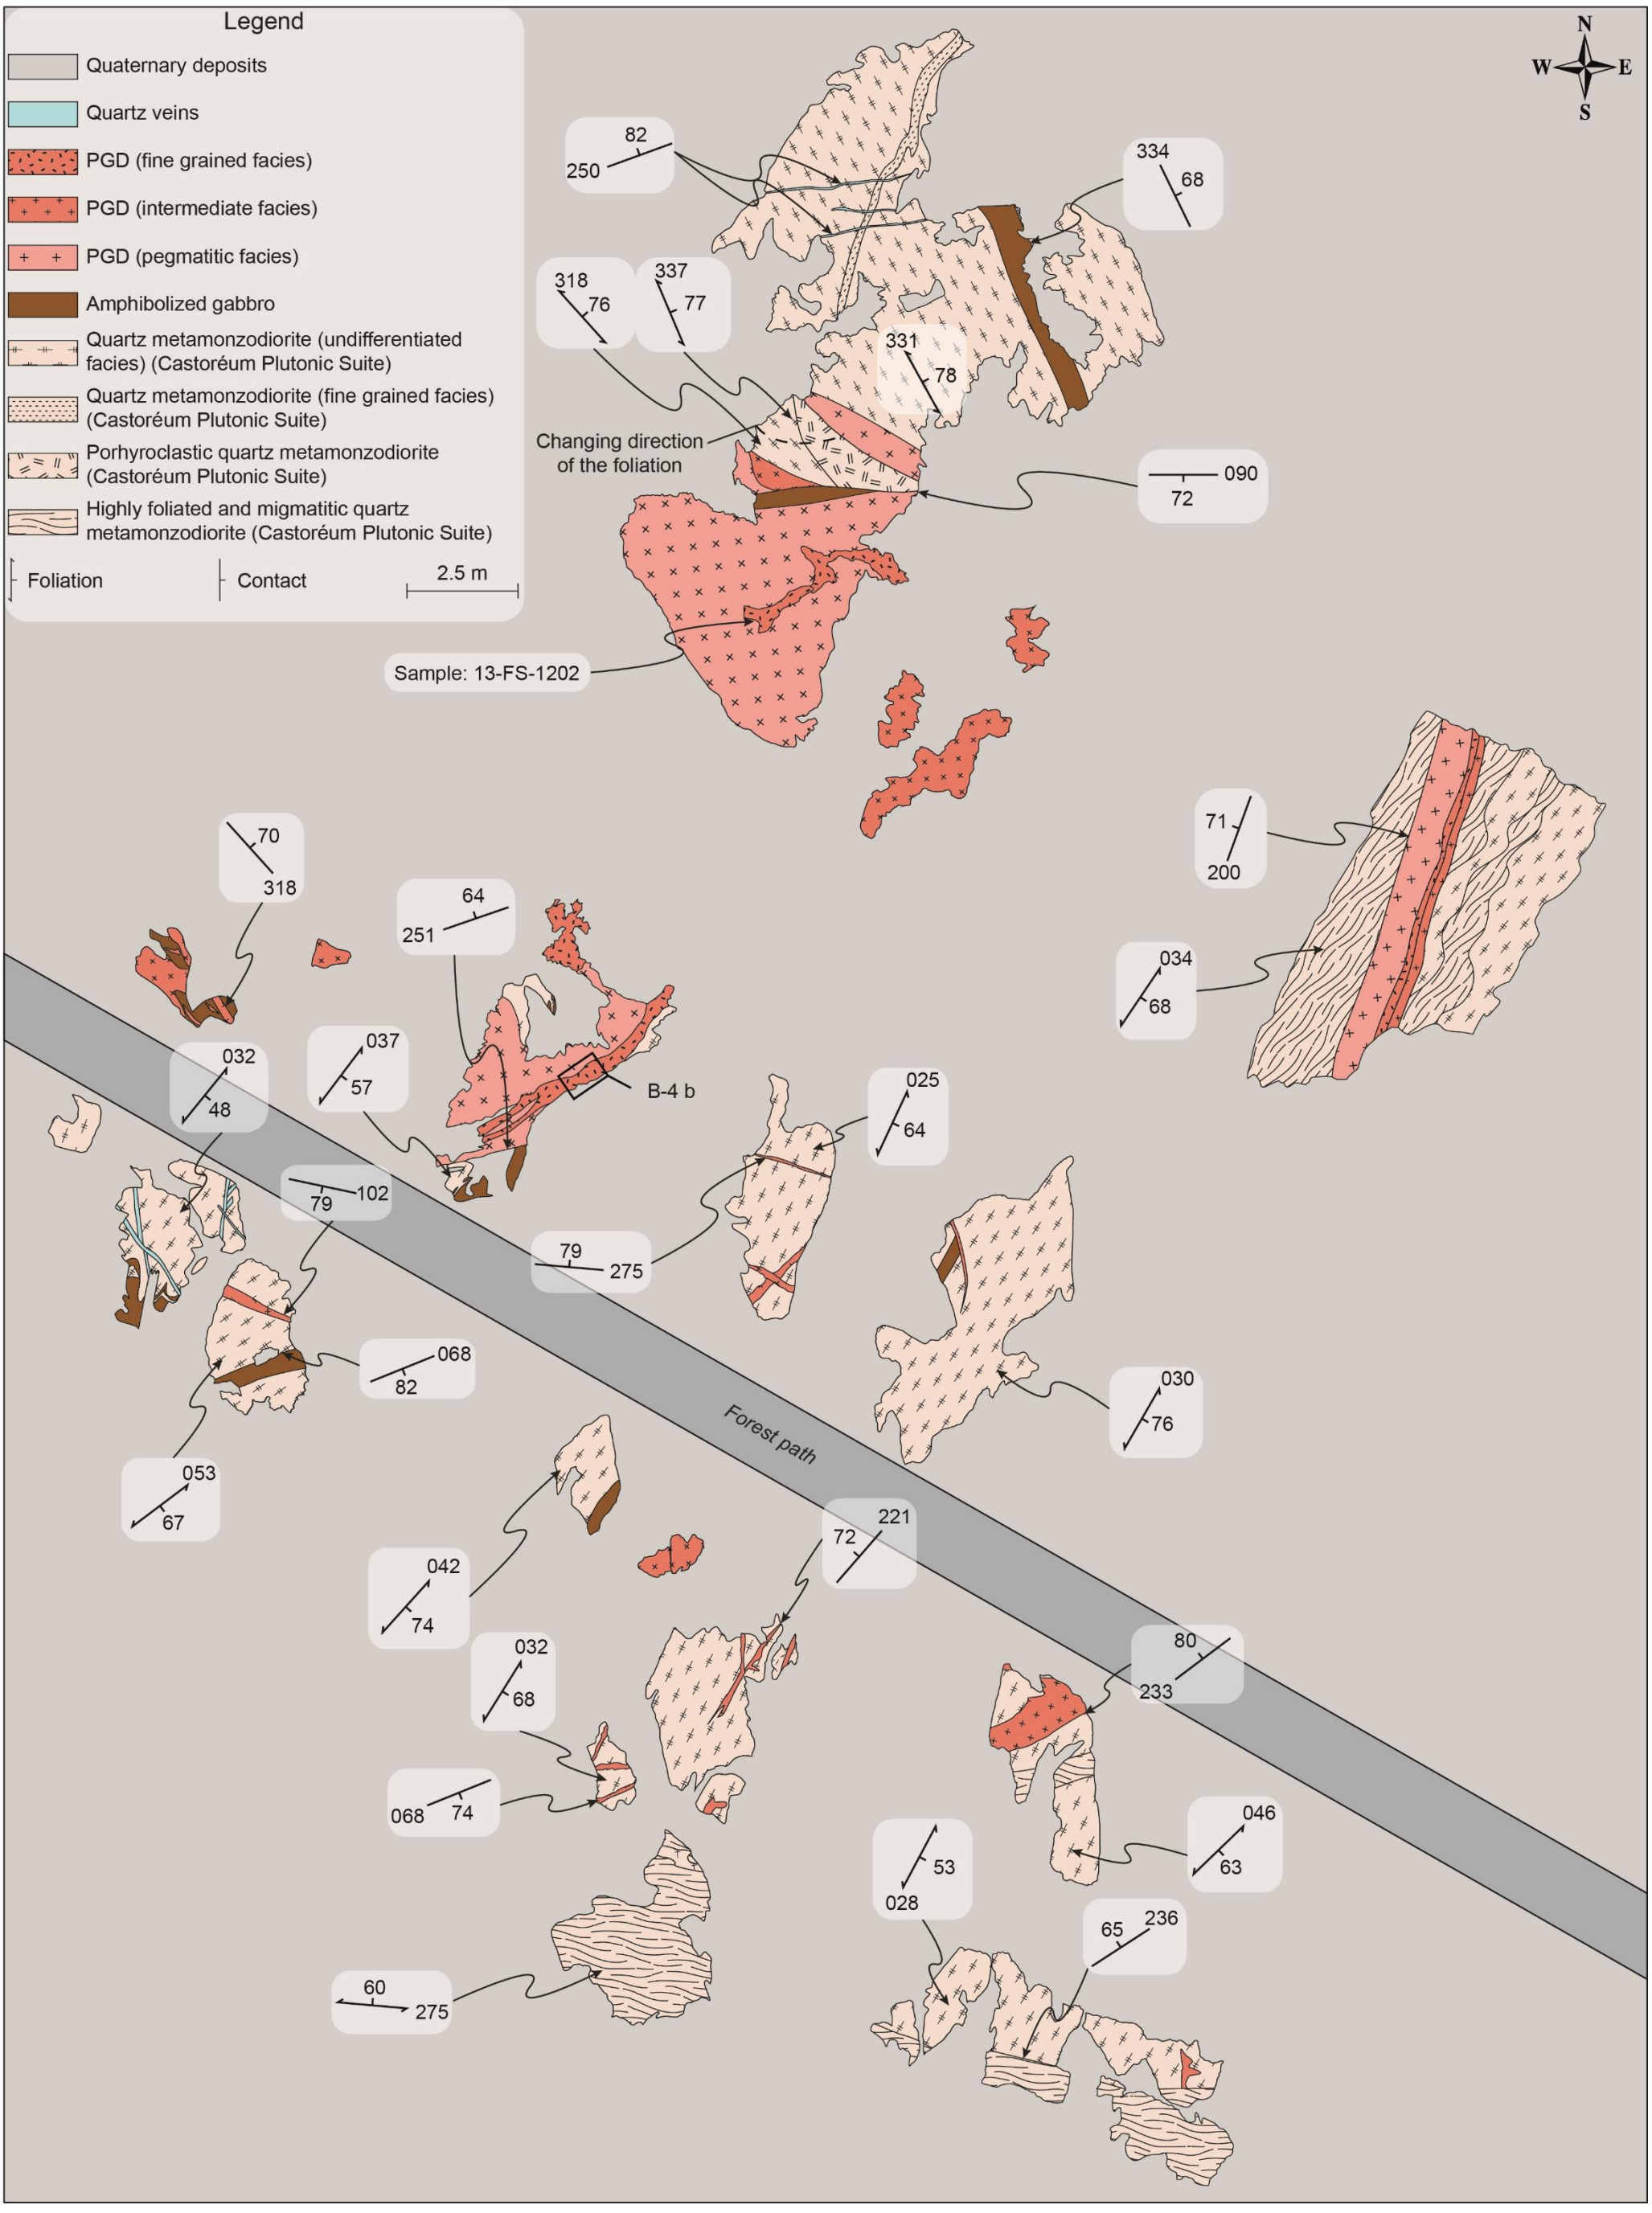

Figure B-3: **Detailed map of the 13-FS-1202 outcrop made of a quartz metamonzodiorite from the Castoréum Plutonic Suite intruded by discordant REE-rich pegmatitic granite dykes. Abbreviation: PGD = pegmatitic granite dyke.**

The dykes are steep-dipping and slightly to strongly discordant to the fabric of the host quartz metamonzodiorite (Fig. 5b). The contacts of the PGD with their hosts are straight or irregular, and are slightly diffuse (over a few millimeters). This dyke is mainly composed of quartz, feldspar and biotite and contains large allanite phenocrysts (>1 cm, Fig. B-4b). The most mineralized zone, i.e. containing the most allanite grains that may reach over 1 cm, corresponds to an intermediate facies which is layered with a pegmatitic (over 3 cm) barren facies at the contact and a finer-grained (0.1-3 cm) allanite-rich facies in the center (Fig. B-4b). The rest of the PGD does not display any sign of organization with random patches ranging from a medium grained allanite-rich facies to a coarse grained barren facies. Coarse grained to pegmatitic facies may locally present allanite aggregates.

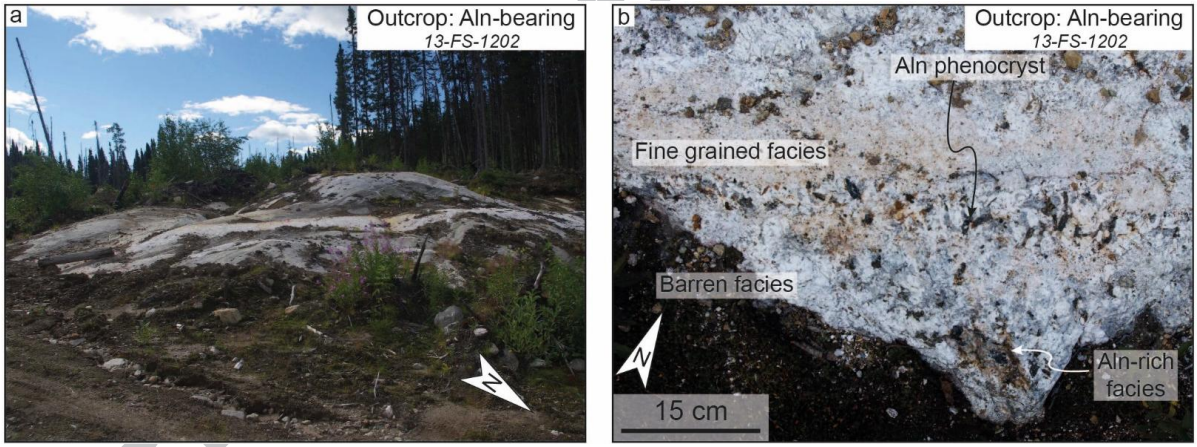

Figure B-4: Photographs of the 13-FS-1202 outcrop from the Lac Okaopéo region. a: general view of the 13-FS-1202 outcrop composed of a pegmatitic granite intruding as a dyke swarm a quartz metamonzodiorite from the Castoréum Plutonic Suite; b: detailed view of the typical zoning observed in the pegmatitic granite. Note that the allanite phenocrysts are associated with an intermediate size grained facies. Abbreviations: Aln = allanite; Aln-bearing = allanite-bearing pegmatitic granite dyke; Qz = quartz.

15. 13-AE-2149 allanite-bearing PGD

The 13-AE-2149 allanite-bearing PGD and REE occurrence is located in the north of the 22K/07 NTS sheet (Fig. 3) and is exposed as a large and steep-dipping outcrop. The detailed map of this outcrop is available in the Fig. B-5. It consists in a main straight pinkish PGD (up to ca. 1 m wide, Figs. B-5 and B-6a) intruding a layered metamangerite from the Castoréum Plutonic Suite.

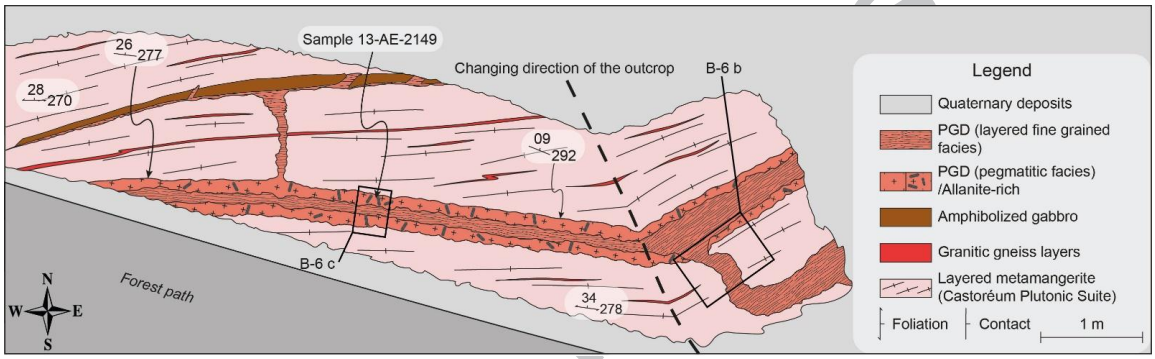

Figure B-5: Detailed map of the 13-AE-2149 outcrop made of a layered metamangerite from the Castoréum Plutonic Suite intruded by a discordant REE-rich pegmatitic granite dyke. Abbreviation: PGD = pegmatitic granite dyke.

This PGD is connected to a network of texturally continuous veins concordant and discordant to the foliation of the host layered metamangerite from the Castoréum Plutonic Suite (Fig. B-6b). The main dyke is shallow-dipping (Fig. 5b) and the contact between the PGD and the metamangerite is slightly discordant to locally sub-concordant and may be very diffuse (Figs. B-6c, 5b).

The upper contact of the dyke is marked by a ca. 20 cm wide pegmatitic facies with a grain size over 10 cm. A few large allanite phenocrysts are disseminated across this contact, and may reach over 10 cm (Fig. B-6c). The core of the dyke is composed of a layered fine grained facies composed of alternating (i) quartz-K-feldspar-rich lenses, and (ii) quartz-plagioclase-rich lenses that are generally not longer than 30 cm (Fig. B-6c). The lower contact of the dyke is similarly marked by a pegmatitic facies up to ca. 45 cm in width (Fig. B-6c).

Allanite phenocrysts are up to ca. 10 cm, with a long axis mainly perpendicular to the walls of the dyke. The lower contact of the dyke with the layered metamangerite is more diffuse than at the upper contact and might reflect melt/crystal segregation (Fig. B-6c).

A few meters away from the contacts with granitic veins, the host layered metamangerite displays a homogeneous texture and structure while close to the contacts, the metamangerite grades into a migmatitic gneiss dominated by K-feldspar and clinopyroxene.

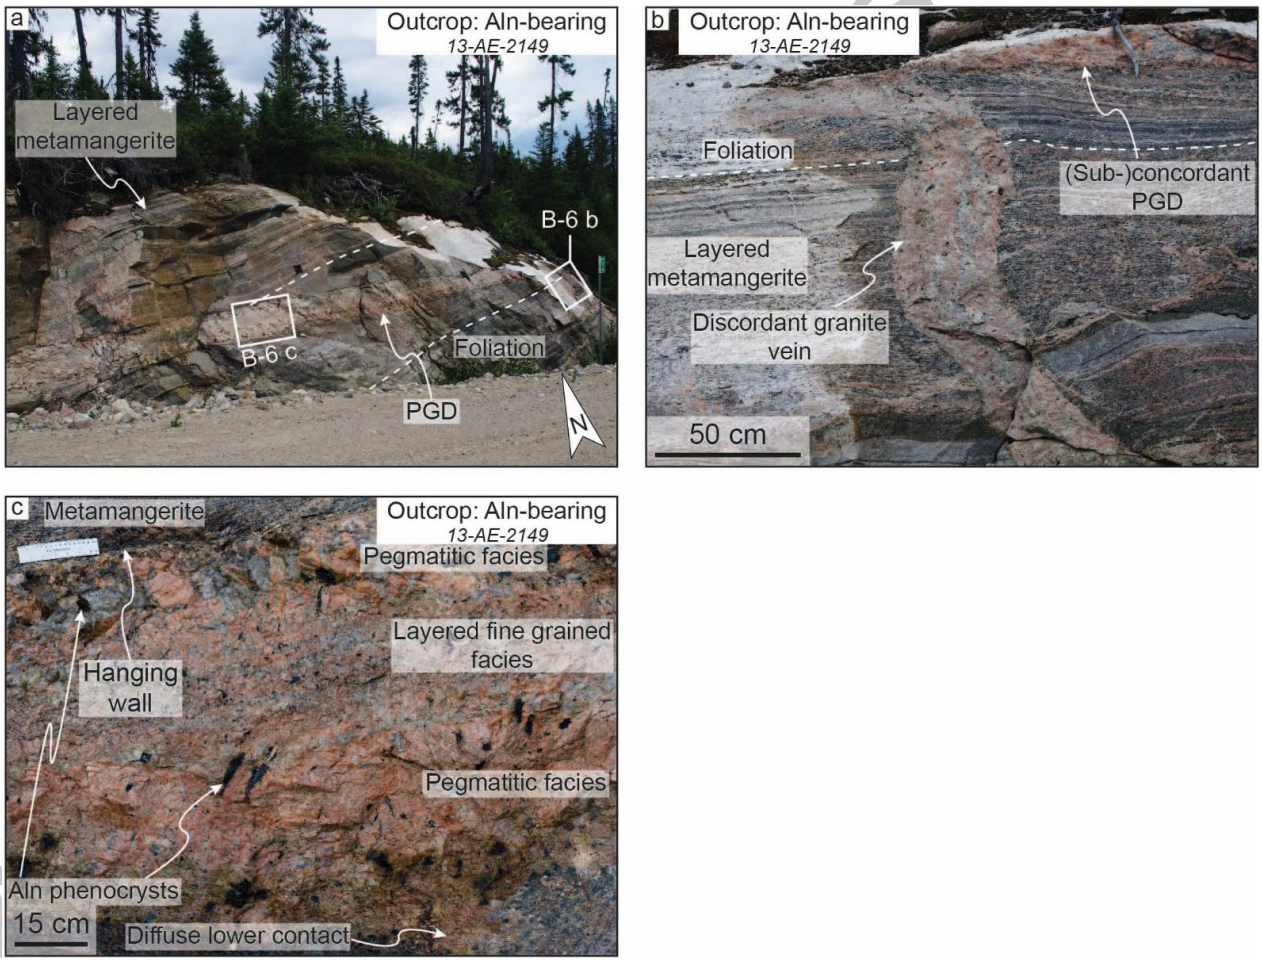

Figure B-6: Photographs of the 13-AE-2149 outcrop from the Lac Okaopéo region. a: general view of the 13-AE-2149 outcrop composed of a pegmatitic granite dyke intruding a layered metamangerite from the Castoréum Plutonic Suite; b: detailed view of one of the pegmatitic granite vein discordant to the foliation of its host rock and its connection with the main pegmatitic granite dyke expressed on this outcrop, here with a sub-concordant contact with the layered metamangerite; c: detailed view of the whole dyke zonation from its upper to its lower contact, both marked by a pegmatitic facies with large allanite phenocrysts, through a layered fine grained facies. Abbreviation: Aln = allanite; Aln-bearing = allanite-bearing pegmatitic granite dyke; PGD = pegmatitic granite dyke.

Figures captions

Figure 1: a: Position of the Grenville orogen in Laurentia. Paleozoic and younger cover omitted (modified from Hoffman, 1989; Rivers, 2008; Rivers et al., 2012). The northern dashed line represents the boundary between Internal and External Paleoproterozoic Laurentia and the southern dashed line represents the Grenville Front (GF). Abbreviations: 1 = exposed Grenville Province, light grey represents the inferred extension of subsurface allochthonous Grenville Province; 2 = Granite-Rhyolite Igneous Province, ca. 1.50-1.34 Ga and reworked equivalents in the Grenville Province; 3 = Mid-Continental Rift system; 4 = Paleoproterozoic orogens, ca. 1.9-1.8 Ga, ca. 1.65 Ga and reworked equivalents in the Grenville Province; 5 = Archean cratons; GF = Grenville Front. b: Simplified tectonic map of the Grenville Province (modified after Rivers, 2008; Rivers et al., 2012). Letters in circle represent the localization of the main Grenvillian granitic pegmatites field as reviewed in Ayres and Černý (1982) and Černý (1990): A = Central Gneiss Belt; B = Central Metasedimentary Belt; C = Central Granulite Terrain; D = eastern part of the Grenville Province. Abbreviations: ABT = Allochthon Boundary Thrust; Cn = Canyon domain; G = Gagnon Terrane; GF = Grenville Front; HJ = Hart-Jaune terrane; L = Lelukuau terrane; Ts = Tshenukutish terrane.

Figure 2: Geological map of the central Grenville (Quebec) showing the position of the studied Lac Okaopéo region (NTS sheets 22K/01, 22K/02, 22K/07, 22K/08, 22K/09, 22K/10, modified after Moukhsil et al., 2014). Abbreviations: ABT = Allochthon Boundary Thrust; MIZ = Manicouagan Imbricate Zone.

Figure 3: Simplified geological map of the studied Lac Okaopéo region (modified after Moukhsil et al., 2014) showing the geology of the environment of the REE occurrences identified in 2013 by Moukhsil et al. (2014). Stars and diamonds represent monazite-bearing and allanite-bearing pegmatitic granite outcrops respectively. Coordinates of the REE

occurrences are proposed in Table 1. [1]: Augland et al. (2015); [2]: Gobeil et al. (2002); [3]: David (2006); [4]: Dunning and Indares (2010); [5]: David et al. (2009); [6]: Moukhsil et al. (2013a); [7]: Moukhsil et al. (2012); [8]: Lasalle et al. (2013). Abbreviation: PGD = pegmatitic granite dyke.

Figure 4: Example of detailed map for the 13-AM-13 monazite-bearing pegmatitic granite outcrop from the Lac Okaopéo region showing the relationships between the different identified facies of the pegmatitic granite and the sampling areas. The detailed map for the six other outcrops are proposed in appendices A and B. Abbreviations: PGD = pegmatitic granite dyke.

Figure 5: Structural measurements of the investigated pegmatitic granite dykes from the Lac Okaopéo region and of the foliation of their host rocks. a: structural measurements from the outcrops of paragneisses-hosted monazite-bearing pegmatitic granite dykes; b: structural measurements from the outcrops of metaplutonic complexes-hosted allanite-bearing pegmatitic granite dykes. Stars and diamonds represent monazite-bearing and allanite-bearing pegmatitic granite outcrops respectively. Note that a larger number of measurements are reported for outcrops of metaplutonic complexes-hosted pegmatitic granite dykes on which allanite-bearing dykes are expressed as dyke swarms. In addition, the concordant/discordant veins connected to the main dyke of the 13-AE-2149 outcrop form a network of undulating veins that do not allow clear 3D observations. Therefore, these veins have not been measured. Abbreviations: Aln-bearing PGD = allanite-bearing pegmatitic granite; Mnz-bearing PGD = monazite-bearing pegmatitic granite.

Figure 6: Representative photographs of the monazite-bearing pegmatitic granite outcrops from the Lac Okaopéo region (from the outcrops 13-AM-07, -13 and 13-TC-5008). a: general view of the 13-AM-13 outcrop composed of a pegmatitic granite intruding paragneisses from the Plus-Value Complex; b: detailed view of Stockscheider-like contact between the 13-AM-

07 pegmatitic granite dyke and the intruded paragneisses marked by the crystallization of feldspar from the dyke perpendicular to the contact; c: locally diffuse contact between the 13-TC-5008 pegmatitic granite dyke and the intruded paragneisses delineated by garnet-biotite aggregates; d: typical transition between the fine and coarse grained facies of the 13-AM-13 pegmatitic granite dyke underlined by biotite aggregates. Note that the abundance of biotite in the fine grained facies on this photograph is related to the vicinity of the coarse grained facies; e: detailed view of a garnet phenocryst in the fine grained facies; f: monazite crystals from the fine grained facies; g: typical pegmatitic facies essentially composed of a quartz+feldspar+biotite assemblage in which feldspar and biotite crystals can reach over 5 cm; h: arborescent textures made by skeletal crystals reaching up to 15 cm long in the 13-TC-5008 pegmatitic granite dyke. Abbreviations: Bt = biotite; Grt = garnet; Fsp = feldspar; Mnz = monazite; Mnz-bearing = monazite-bearing pegmatitic granite; PGD = pegmatitic granite dyke; Qz = quartz.

Figure 7: Representative photographs of the allanite-bearing pegmatitic granite outcrops from the Lac Okaopéo region (from the outcrops 13-TC-5072, 13-FS-1202 and 13-AE-2149). a: general view of the dome-shaped 13-TC-5072 outcrop composed of a pegmatitic granite intruding as a dyke swarm a metamonzogranite from the Bardoux Plutonic Suite; b: detailed view of the typical zoning observed in the 13-FS-1202 pegmatitic granite. Note that the allanite phenocrysts are associated with a coarse grained facies; c: typical dyke zonation of the 13-TC-5072 pegmatitic dykes, with a southeastern boundary (1) marked by a thin zone of reaction with the host rock developed over a few millimeters with almost no biotite, followed by a fine grained facies with increasing grain size and proportions of biotite (2, 3) up to a pegmatitic core (4). This core is followed by a progressive fine grained facies with decreasing grain size zone (5). The northern contact (6) is marked by the development of K-feldspar phenocrysts perpendicular to the contact. Note that these phenocrysts are locally disconnected

to the contact that contrast with a Stockscheider-like texture as represented in Fig. 6b, and that dyke is discordant to the foliation of the intruded metamonzogranite; d: typical allanite phenocrysts in pegmatitic granite dykes intruding the metamonzogranite; e: general view of the 13-AE-2149 outcrop composed of a pegmatitic granite dyke intruding a layered metamangerite from the Castoréum Plutonic Suite; f: detailed view of one of the pegmatitic granite vein from the 13-AE-2149 outcrop discordant to the foliation of its host rock and its connection with the main pegmatitic granite dyke expressed on this outcrop, here with a sub-concordant contact with the layered metamangerite; g: detailed view of the whole 13-AE-2149 shallow-dipping dyke zonation from its hanging wall to its lower contact, both marked by a pegmatitic facies with large allanite crystals, through a layered fine grained facies making the core of the core of the dyke and that also carries disseminated and smaller allanite grains. Abbreviations: Aln = allanite; Aln-bearing = allanite-bearing pegmatitic granite; Bt = biotite; K-Fsp = K-feldspar; PGD = pegmatitic granite dyke.

Figure 8: Typical petrography of monazite-bearing pegmatitic granite dykes from the Lac Okaopéo region. a: major phases composing the monazite-bearing granite (polarized and analysed light); b: syn- to late-zircon growth monazite crystal (SEM); c: late-magmatic crystallization of Th-U±REE silicates filling fractures of monazite crystals (SEM); d: late-sericite affecting plagioclase (polarized and analysed light). Abbreviations: Bt = biotite; Mc = microcline; Mnz = monazite; Mnz-PGD = monazite-bearing pegmatitic granite dyke; Pl = plagioclase; Qz = quartz; Ser = sericite; Silic. = silicates; Zrc = zircon.

Figure 9: Chemical mapping of monazite grains from the 13-AM-13 and 13-TC-5008 monazite-bearing pegmatitic granite dykes from the Lac Okaopéo region. Numbers in figures a and d refer to the U-Pb dating analyses conducted using LA-ICP-MS, and reported in Table 5. a to c: BSE image with spot positions of LA-ICP-MS U-Pb dating and Ce and Th X-ray

458 maps of a representative oscillatory zoned monazite grain from the 13-AM-13 monazite-
459 bearing pegmatitic granite; d to f: BSE image with spot positions of LA-ICP-MS U-Pb dating
460 and Ce and Th X-ray maps of a representative rather homogeneous and weakly zoned
461 monazite grain from the 13-TC-5008 monazite-bearing pegmatitic granite. Abbreviations:
462 Mnz = monazite Mnz-PGD = monazite-bearing pegmatitic granite dyke.

463 **Figure 10:** Chemical compositions of the different zones identified in monazite grains from
464 the 13-AM-13 and 13-TC-5008 pegmatitic granite samples from the Lac Okaopéo region. a:
465 ternary plot of the monazite compositions from the 13-AM-13 monazite-bearing pegmatitic
466 granite. For the three identified zones, the monazite grains are dominated by monazite-(Ce)
467 compositions, but evolve towards monazite-(La) compositions with increasing Th and Si
468 proportion over LREE and P; b: Th+U+Si vs REE+Y+P diagram with compositional trends of
469 huttonite and brabantite end-members for monazite grains from the 13-AM-13 pegmatitic
470 granite. The huttonite substitution tends to be dominant with increasing Th and Si proportion
471 over LREE and P; c: ternary plot of the monazite compositions from the 13-TC-5008
472 monazite-bearing pegmatitic granite. For the three identified zones, the monazite grains are
473 clustered into the monazite-(Ce) composition field with no significant changes with increasing
474 Ti and Si proportion over LREE and P; d: Th+U+Si vs REE+Y+P diagram with
475 compositional trends of huttonite and brabantite end-members for monazite grains from the
476 13-TC-5008 pegmatitic granite. Note these grains are mainly characterized by the huttonite
477 end-member with no significant changes with increasing Ti and Si proportion over LREE and
478 P. Abbreviations: Mnz = monazite; PGD = pegmatitic granite dyke.

479 **Figure 11:** Typical petrography of allanite-bearing pegmatitic granite dykes from the Lac
480 Okaopéo region. a: major phases composing the allanite-bearing granite dykes (polarized and
481 analysed light); b: allanite crystal displaying an Aln_1 oscillatory zoned core corroded by an

Aln_2 overgrowth of similar composition (Table 4) and altered by a rim associated with fluids circulation probably related to the magmatic-hydrothermal transition (polarized and analysed light); c: allanite grains display rims probably associated with the late-sericitization of feldspar. Note the syn- to late-zircon growth crystallization of the allanite phenocrysts (polarized and analysed light); d: typical millimetric allanite phenocryst from the 13-FS-1202 pegmatitic granite showing LREE-rich and Fe-Ca-LREE(Ce)-rich zones (Table 4) surrounded by an alteration rim probably associated with fluids circulation probably related to the magmatic-hydrothermal transition; e: veinlets of Ca+REE carbonates on the boundary or filling fractures of allanite crystals most probably associated with fluids circulation at the magmatic-hydrothermal transition (SEM); f: veinlets of Ca+REE silicates on the boundary or filling fractures of allanite crystals most probably associated with fluids circulation at the magmatic-hydrothermal transition (SEM). Abbreviations: Aln = allanite; Aln-PGD = allanite-bearing pegmatitic granite dyke; Bt = biotite; Carb. = carbonates; Mc = microcline; Pl = plagioclase; Qz = quartz; Ser = sericite; Silic. = silicates; Zrc = zircon.

Figure 12: Chemical compositions of the different zones identified in allanite grains from the 13-TC-5072 and 13-FS-1202 pegmatitic granite samples from the Lac Okaopéo region. a: REE vs Al composition of allanite grains from the 13-TC-5072 allanite-bearing pegmatitic granite obtained on EMP (Petrík et al., 1995). Note the clustering of compositions of the different zones close to the allanite pole; b: REE vs Al composition of allanite grains from the 13-FS-1202 allanite-bearing pegmatitic granite obtained on EMP (Petrík et al., 1995). Note the alteration trend that lead to more 'epidote like' compositions. Abbreviation: Aln = allanite; PGD = pegmatitic granite dyke.

Figure 13: Whole rock geochemistry of the REE-richest facies of the investigated pegmatitic granite dykes from the Lac Okaopéo region, compared to data of REE-rich granitic

pegmatites samples from Lentz (1996). a: peraluminous, metaluminous and peralkaline fields showing the peraluminous character of the pegmatitic granite samples; b: chondrite normalized REE patterns of the pegmatitic granite samples. Note that six of them display a similar tendency of strong fractionation of LREE over HREE that contrast with lower fractionation of the 13-AE-2149 dyke. The ΣREE increases with decreasing Eu/Eu* (normalization after McDonough and Sun, 1995); c: U+Th (ppm) vs ΣREE (ppm) diagram showing the close relationship between an increase in REE and an increase in U and Th for all the investigated pegmatitic granite samples; d: Na_2O (wt.%) vs CaO (wt.%) diagram that evidence a coeval increase of Na_2O, CaO and the REE associated with a decrease in K_2O for all the investigated pegmatitic granite samples; e: Nb/Ta vs Zr/Hf diagram showing a contradictory behavior of Nb and Ta between the monazite-bearing and the allanite-bearing samples, as Nb/Ta increases with the ΣREE in the former and decreases with the ΣREE in the latter. Note that the Zr/Hf ratio remain quite stable for both series; f: CaO (wt.%) vs P_2O_5 (wt.%) diagram showing that the formation of monazite (Mnz-bearing pegmatitic granite samples) is associated with increasing CaO and P_2O_5 contents. Note that the Aln-bearing pegmatitic granite samples do not display a similar pattern; g: $Fe_2O_{3\ (total)}$ (wt.%) vs MgO (wt.%) diagram showing that the formation of allanite (Aln-bearing pegmatitic granite samples) is associated with increasing Fe_2O_3 and MgO contents. Note that the Mnz-bearing pegmatitic granite samples do not display a similar pattern. Abbreviation: PGD = pegmatitic granite dyke.

Figure 14: U-Pb ages of monazite grains from the 13-AM-13 and 13-TC-5008 pegmatitic granite dykes from the Lac Okaopéo region. a: Concordia plots for the monazite grains from the 13-AM-13 pegmatitic granite (n = 25, data-point error ellipses are 2σ); b: Concordia plots for the over 98% of concordance analyses from the 13-AM-13 pegmatitic granite (n = 11,

data-point error ellipses are 2σ); c: Concordia plots for the monazite grains from the 13-TC-5008 granite (n = 22, data-point error ellipses are 2σ).

533

534 **Table 1:** Location, present coordinates and results presented in this study of the REE
535 occurrences from the Lac Okaopéo region, first ordered by type of occurrence then from north
536 to south. Abbreviation: Aln-bearing = allanite-bearing pegmatitic granite dyke; Mnz-bearing
537 = monazite-bearing pegmatitic granite dyke; NTS = National Topographic System.

Table 4: Analyses of allanite grains from the 13-TC-5072 and 13-FS-1202 pegmatitic granite dykes from the Lac Okaopéo region. Data were obtained using EMP and were performed on LREE(Ce)-rich zones, intermediate zones and alteration rims of allanite grains from the 13-TC-5072 pegmatitic granite, and on LREE(Ce)-rich zones, Fe-Ca-LREE(Ce)-rich zones and alteration rims of allanite grains from the 13-FS-1202 pegmatitic granite. They are reported with confidence interval of 95% in brackets (n = number of analyses). Abbreviations: Aln = allanite.

575

576 **Table 6:** Summary of the main characteristics of the REE-rich pegmatitic granite dykes from
577 the Lac Okaopéo region, first ordered by type of occurrence then from north to south.
578 Abbreviations: Aln-bearing = allanite-bearing pegmatitic granite dyke; ASI = Aluminum
579 Saturation Index given by the expression ASI = Al/(Ca – 1.67 x P + Na + K) (Frost et al.,
580 2001; Shand, 1943); Mnz-bearing = monazite-bearing pegmatitic granite dyke.

Type of REE occurrence	**Outcrop n°**	**Field expression**	**Dip**	**Contact**	**Texture (from contact towards core)**	**Accessory minerals**[1]	**Geochemical features**	**Geochronology (U-Pb on monazite)**	
						Type	**REE-bearing phase composition**		
Mnz-bearing	**13-AM-07**	Single dyke	Steep-dipping	Slightly diffuse – Discordant	Stockscheider contact – fine-grained – pegmatitic	Zircon-monazite	-	*High:* ASI, ΣLREE, La_N/Yb_N, Th, Zr/Hf, Zr and Hf, Nb/Ta *Low:* ΣHREE, Eu/Eu*, Nb and Ta *Positive correlation:* P_2O_5 and CaO with ΣREE	-
	13-AM-10	Single dyke	Steep-dipping		Fine-grained	Zircon-monazite	-		-
	13-AM-13	Single dyke	Steep-dipping		Patchy zoning (fined grained to pegmatitic)	Zircon-monazite-(Ce)(-minor garnet and Ti-oxides)	LREE-rich cores/Th-Si-rich overgrowths		996.7±5.3 Ma
	13-TC-5008	Single dyke	Steep-dipping	Locally diffuse – Discordant	Patchy zoning (coarse-grained to skeletal Bt-rich)	Zircon-monazite-(Ce)(-minor garnet)	Rather homogeneous		1005.4±4.4 Ma
Aln-bearing	**13-TC-5072**	Dyke swarm	Steep-dipping	Slightly diffuse – Discordant to sub-concordant	Fine-grained – pegmatitic	Zircon-allanite-(Ce)	Homogeneous cores – Fe-rich rims	*High:* ASI, ΣLREE, La_N/Yb_N, Th, Zr/Hf, Zr and Hf, Nb/Ta *Low:* ΣHREE, Eu/Eu*, Nb and Ta *Positive correlation:* Fe_2O_3 (total) and MgO with ΣREE	-
	13-FS-1202	Dyke swarm	Steep-dipping	Slightly diffuse – Discordant	Patchy to layered zoning (fined grained to	Zircon-allanite-(Ce)	LREE-rich – Fe-Ca-LREE-rich cores – Si-rich/LREE-		-

					pegmatitic)		poor rims		
	13-AE-2149	Single dyke connected to concordant/discordant veins	Shallow-dipping	Very diffuse – Discordant to sub-concordant	Pegmatitic contacts – fine-grained core	Zircon-allanite(-rare apatite)	-	*Lower*[2]: ASI, La_N/Yb_N, Nb/Ta, Eu/Eu* *Higher*[2]: ΣLREE, ΣHREE, Zr and Hf, Nb and Ta *Intermediate*[2]: Th, Zr/Hf	-

[1] All samples are dominated by a quartz+K-feldspar+plagioclase±biotite assemblage.

[2] In comparison with the other dykes investigated in this study.

584 **Appendix C:** Planar fabrics measured on the pegmatitic granite dykes from the Lac Okaopéo
585 region, first ordered by type of occurrence then from north to south. Planar structures are
586 plotted in stereograms in Fig. 5 and are represented on detailed mapping of each outcrop from
587 Appendices A and B.

591 **Appendix D:** Operating conditions for the LA-ICP-MS equipment

	U-Pb monazite analyses
Laboratory & Sample Preparation	
Laboratory name	Géosciences Rennes, UMR CNRS 6118, Université Rennes 1, Rennes, France
Sample type/mineral	Magmatic monazite
Sample preparation	Thin-sections
Imaging	Hitachi S-4800 SEM, GeoRessources, UMR 7359, Université de Lorraine, Vandœuvre-lès-Nancy, France
Laser ablation system	
Make, Model & type	ESI NWR193UC, Excimer
Ablation cell	ESI NWR TwoVol2
Laser wavelength	193 nm
Pulse width	< 5 ns
Fluence	6.5 J/cm-2
Repetition rate	2 Hz
Spot size	10 µm (round spot)
Sampling mode / pattern	Single spot
Carrier gas	100% He, Ar make-up gas and N_2 (3 ml/mn) combined using in-house smoothing device
Background collection	20 seconds
Ablation duration	60 seconds
Wash-out delay	10 seconds
Cell carrier gas flow (He)	0.75 l/min
ICP-MS Instrument	
Make, Model & type	Agilent 7700x, Q-ICP-MS
Sample introduction	Via conventional tubing
RF power	1350W
Sampler, skimmer cones	Ni
Extraction lenses	X type
Make-up gas flow (Ar)	0.87 l/min
Detection system	Single collector secondary electron multiplier
Data acquisition protocol	Time-resolved analysis
Scanning mode	Peak hopping, one point per peak
Detector mode	Pulse counting, dead time correction applied, and analog mode when signal intensity > ~ 10^6 cps
Masses measured	^{204}(Hg + Pb), ^{206}Pb, ^{207}Pb, ^{208}Pb, ^{238}U
Sensitivity / Efficiency	25000 cps/ppm Pb (50µm, 10Hz)
Dwell time per isotope	10-30 ms depending on the masses
Data Processing	
Gas blank	20 seconds on-peak
Calibration strategy	Moacir Monazite used as primary reference material, Manangoutry Monazite used as secondary reference material (quality control)
Reference Material info	Moacir (Gasquet et al., 2010)
Manangoutry (Paquette and Tiepolo, 2007)	
Data processing package	Glitter (Van Achterbergh et al., 2001)
Quality control / Validation	Manangoutry: 554.8 ± 4.2 Ma (MSWD=0.94; n=8) (sample 13-AM-13)
554.4 ± 3.4 Ma (MSWD=0.94; n=8) (sample 13-TC-5008)

Figure 1 (black and white; 2 columns fitting)

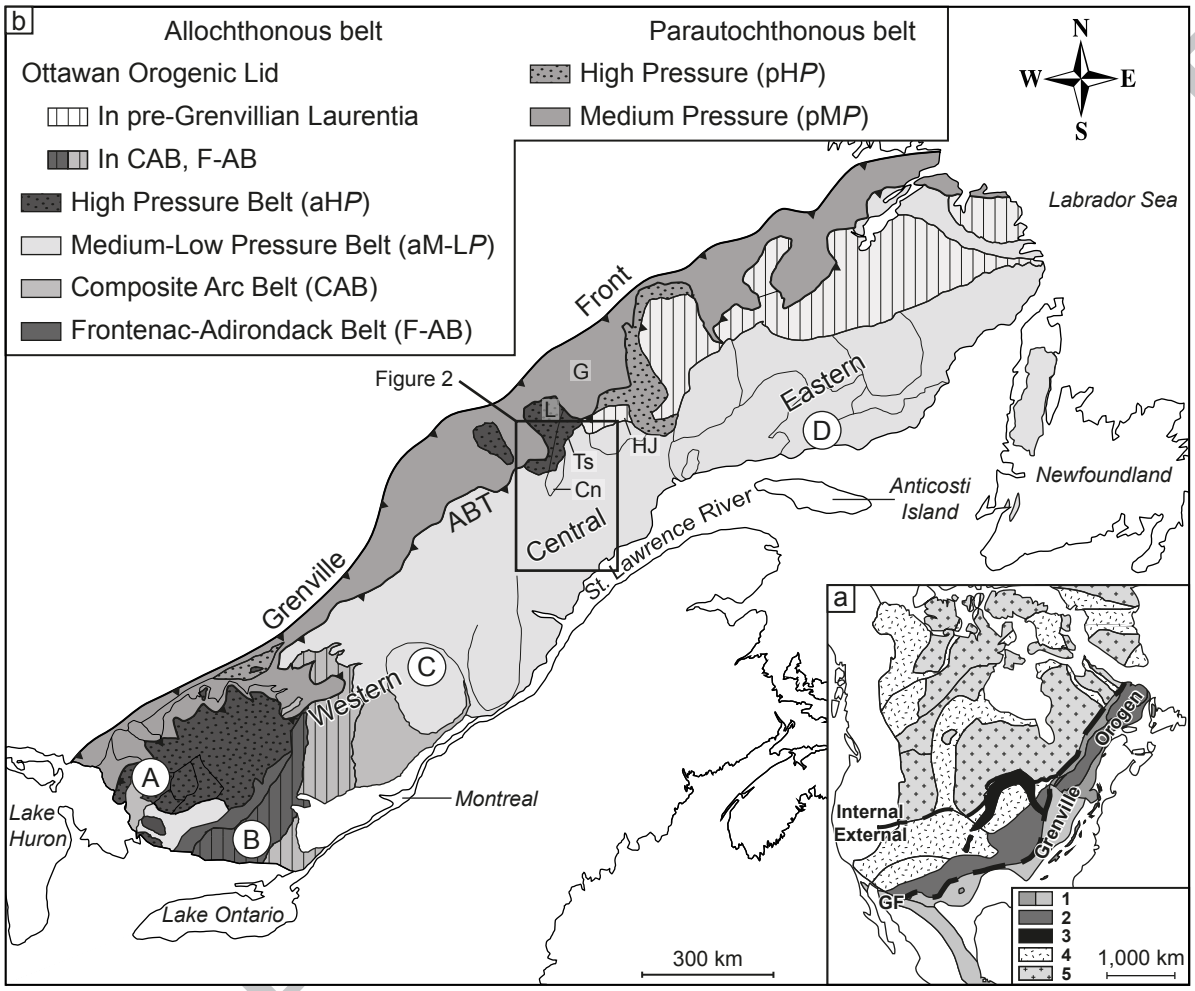

Figure 2 (color; 2 columns fitting)

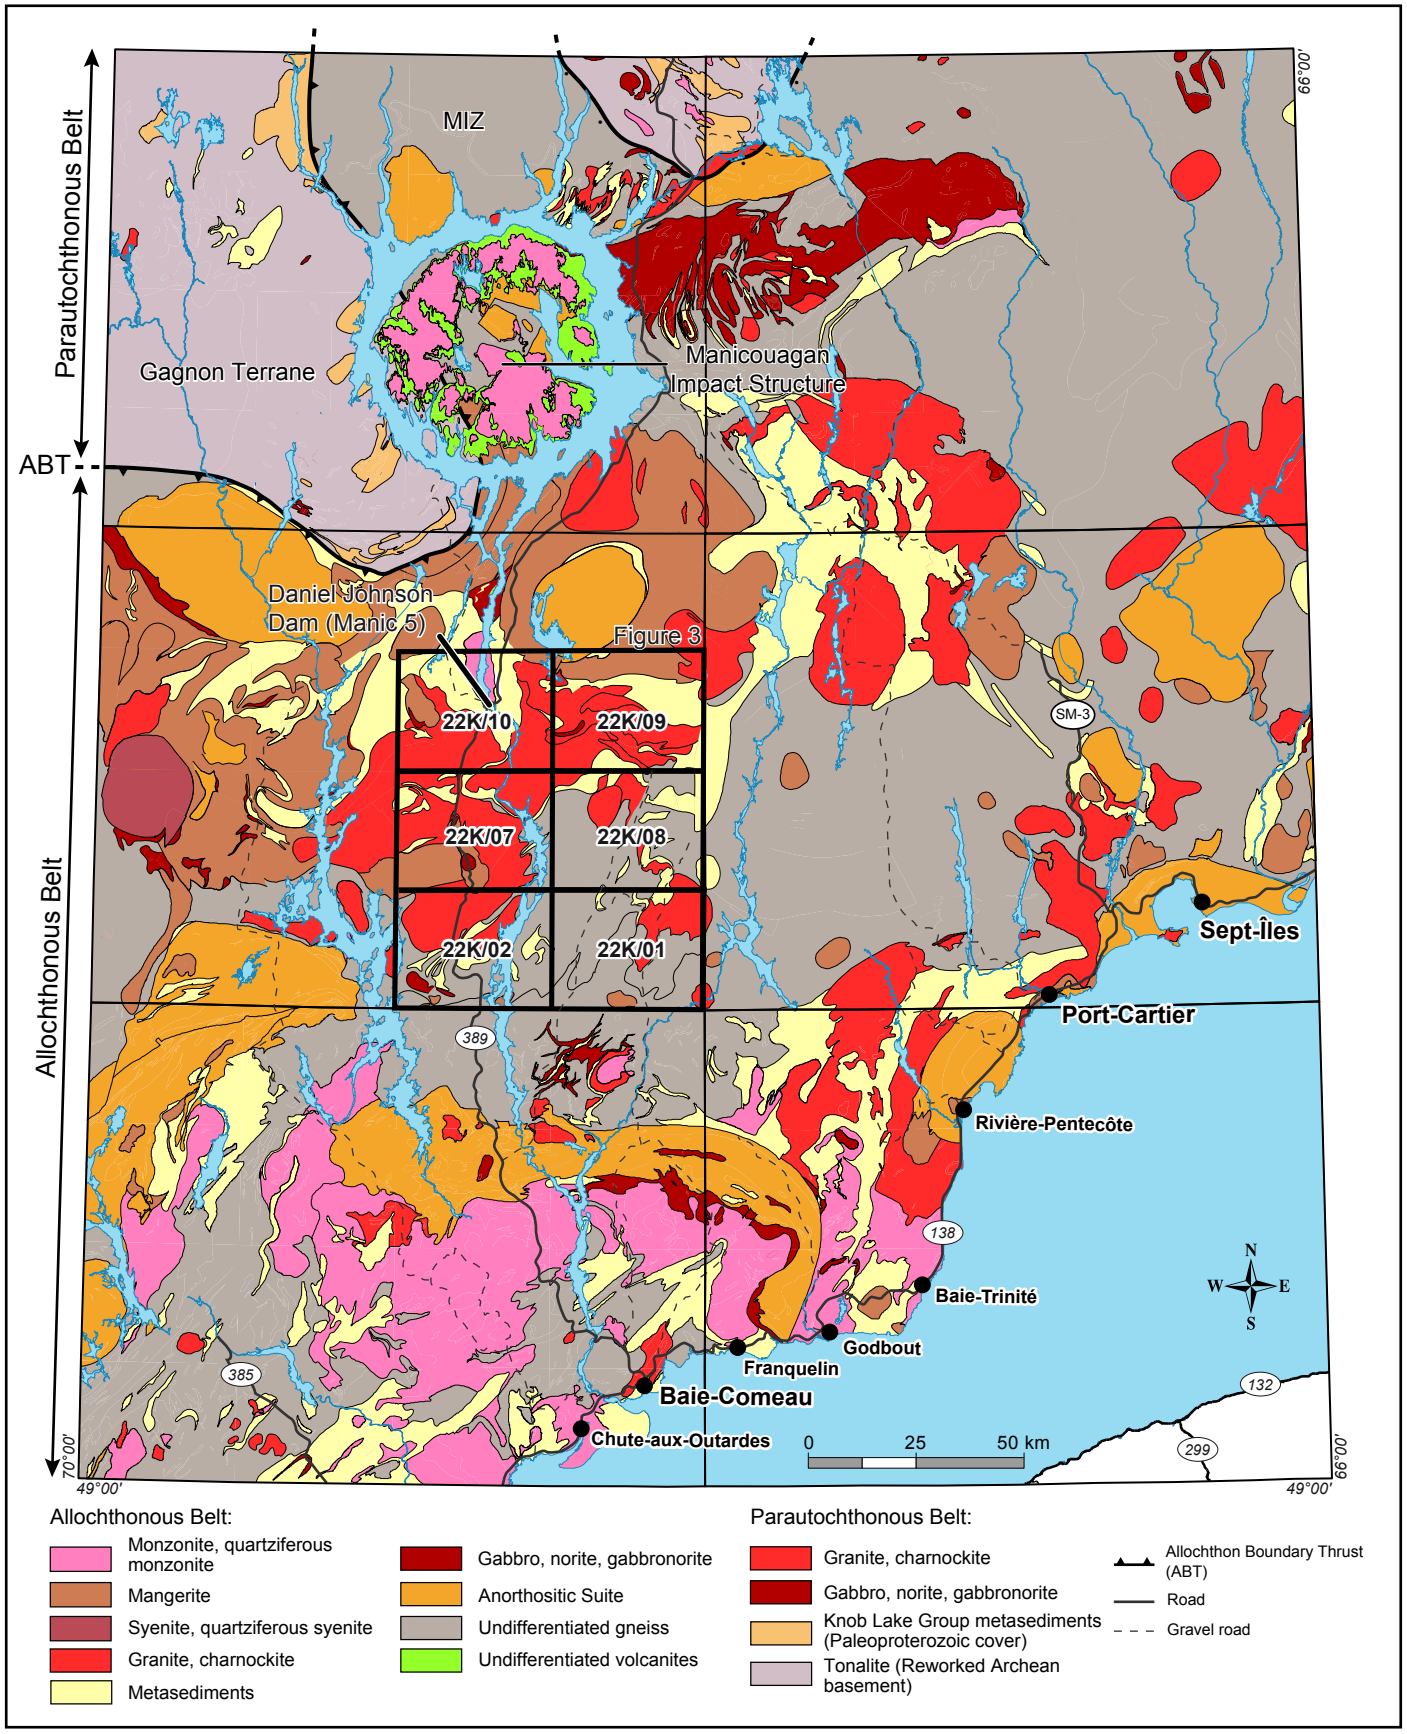

Figure 3 (color; 2 columns fitting)

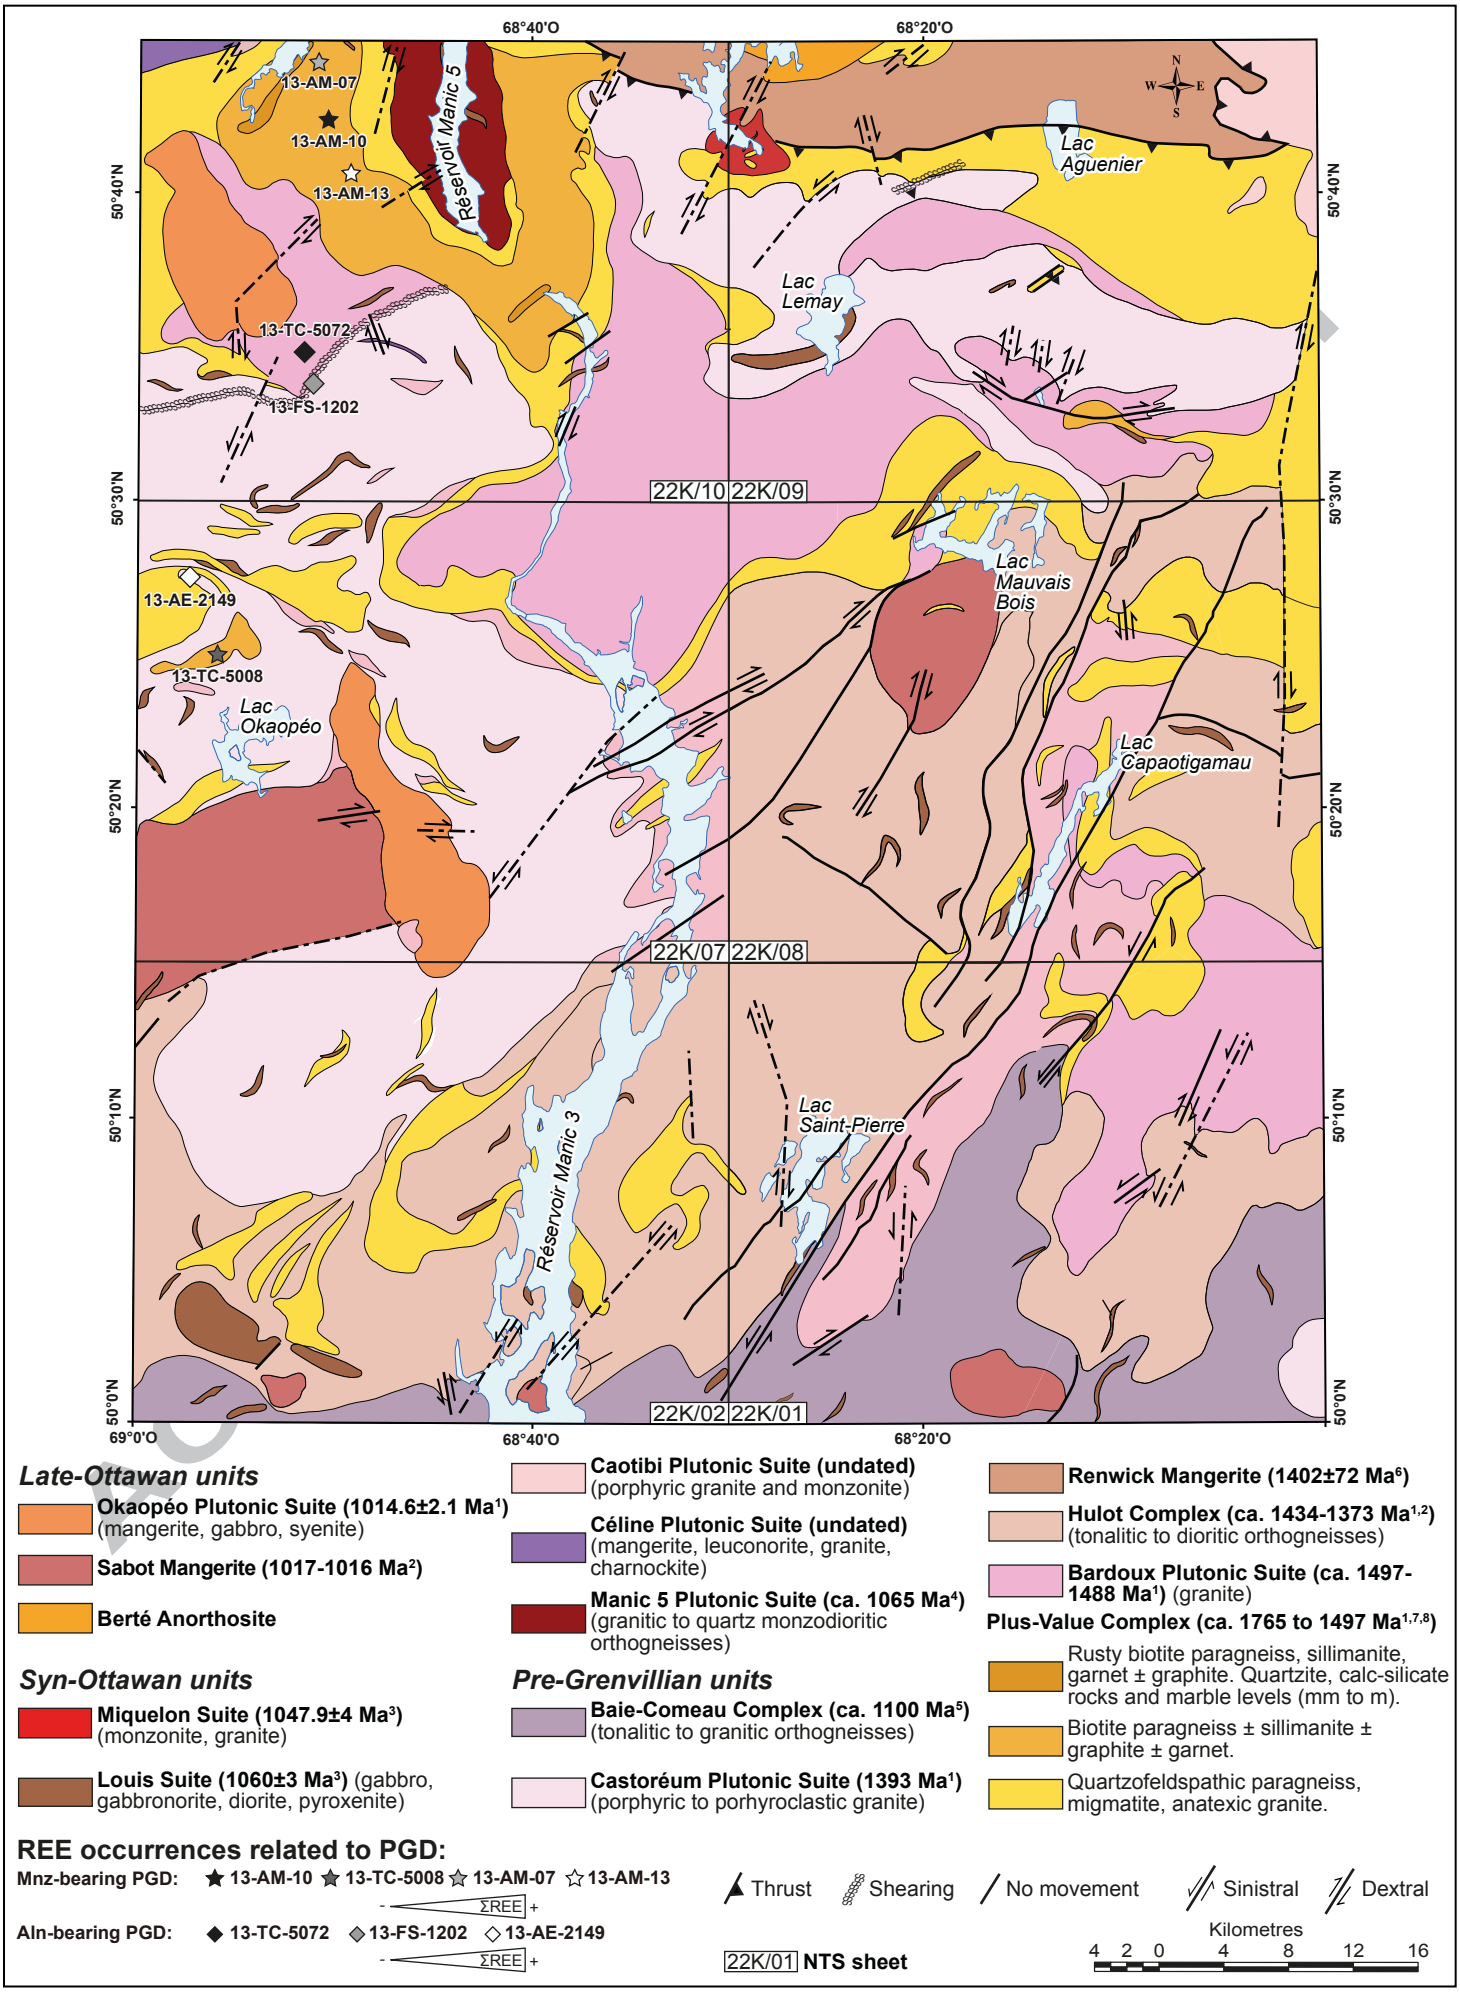

Late-Ottawan units

Okaopéo Plutonic Suite (1014.6±2.1 Ma[1]) (mangerite, gabbro, syenite)

Sabot Mangerite (1017-1016 Ma[2])

Berté Anorthosite

Syn-Ottawan units

Miquelon Suite (1047.9±4 Ma[3]) (monzonite, granite)

Louis Suite (1060±3 Ma[3]) (gabbro, gabbronorite, diorite, pyroxenite)

Caotibi Plutonic Suite (undated) (porphyric granite and monzonite)

Céline Plutonic Suite (undated) (mangerite, leuconorite, granite, charnockite)

Manic 5 Plutonic Suite (ca. 1065 Ma[4]) (granitic to quartz monzodioritic orthogneisses)

Pre-Grenvillian units

Baie-Comeau Complex (ca. 1100 Ma[5]) (tonalitic to granitic orthogneisses)

Castoréum Plutonic Suite (1393 Ma[1]) (porphyric to porhyroclastic granite)

Renwick Mangerite (1402±72 Ma[6])

Hulot Complex (ca. 1434-1373 Ma[1,2]) (tonalitic to dioritic orthogneisses)

Bardoux Plutonic Suite (ca. 1497-1488 Ma[1]) (granite)

Plus-Value Complex (ca. 1765 to 1497 Ma[1,7,8])

Rusty biotite paragneiss, sillimanite, garnet ± graphite. Quartzite, calc-silicate rocks and marble levels (mm to m).

Biotite paragneiss ± sillimanite ± graphite ± garnet.

Quartzofeldspathic paragneiss, migmatite, anatexic granite.

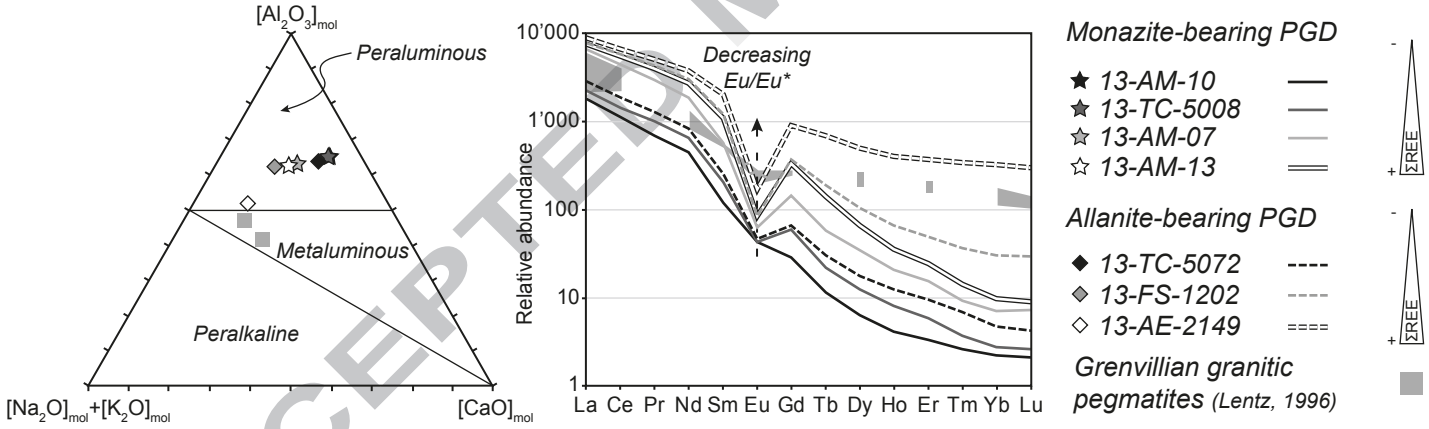
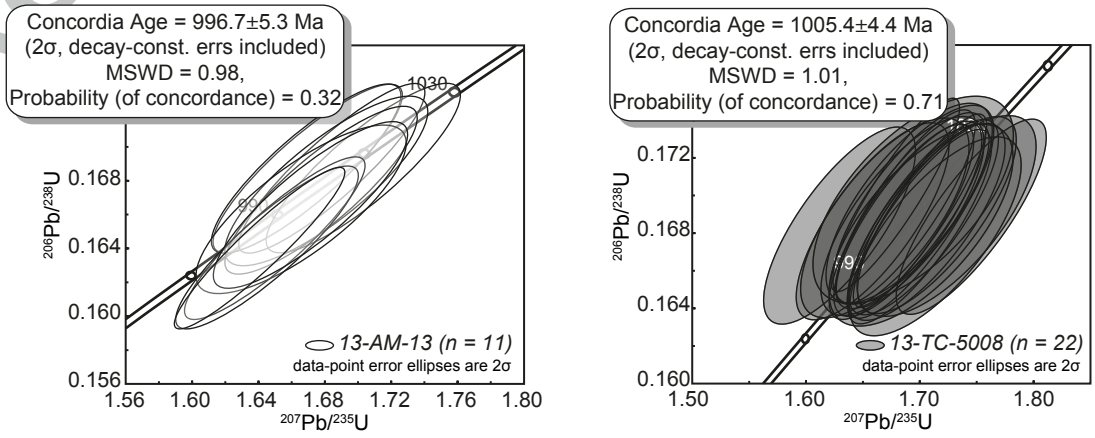
Whole-rock geochemistry of the Mnz- and Aln-bearing PGD



U-Pb dating of magmatic monazite (LA-ICP-MS)



Research highlights:

- ✓ New LREE occurrences associated with peraluminous pegmatitic granite dykes in the central Grenville
- ✓ Unusual LREE mineralization hosted either in monazite (paragneiss-hosted pegmatitic granite) or allanite (meta-igneous complexes-hosted pegmatitic granite)
- ✓ A peraluminous character associated with a peralkaline behavior of trace elements and in contrast with the formation of allanite
- ✓ First evidence of monazite-only LREE mineralization in a pegmatitic granite in the Grenville Province
- ✓ A post-tectonic emplacement in the Allochthonous Belt associated with the initiation of the crustal thickening of the underlying Parautochthonous Belt
