Abstract: We present data available on rare metal and indium distributions in cassiterite and associated minerals from thirteen Sn ± W granite-related ore deposits in the western Variscan Belt (Massif Central and Armorican Massif, France; Galicia, Spain; and SW England). Cassiterite and associated minerals including sulfides and titanium oxides were analysed using an electron probe micro-analyzer (EPMA). Significant indium contents were only measured in cassiterite from hydrothermal vein-type mineralizations associated with peraluminous granites of Montbelleux, Abbaretz (French Armorican Massif) and Marcofán (Galicia); they correlate with the highest Nb, Ta and Fe substitutions. Two coupled substitutions are proposed: (1) $2(\text{Sn}^{4+}, \text{Ti}^{4+}) \leftrightarrow (\text{Fe}^{3+}, \text{In}^{3+}) + (\text{Nb}^{5+}, \text{Ta}^{5+})$ and (2) $\text{Fe}^{2+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow \text{In}^{3+} + (\text{Ti}, \text{Sn})^{4+}$ depending on Fe valence state. Sulfides (stannite, chalcopyrite, pyrite, arsenopyrite and sphalerite) and rutile associated with cassiterite contain significant amounts of indium, even when cassiterite is indium-free, suggesting preferential partitioning into the sulfides.

Key-words: cassiterite; tin; indium; tungsten; ore deposit; trace element; sulphides; mineral chemistry.

1. Introduction

The element indium (In) was discovered by Ferdinand Reich and Theodor Richter in 1863 at the Bergakademie Freiberg in polymetallic Ag-base metal ores of the local Freiberg district (Erzgebirge, Germany) with a spectrograph (Seifert & Sandmann, 2006). Indium is a chalcophile element used in industry for its semiconductor and optoelectronic performance. Due to its softness, In alloys can be plated onto metal or evaporated onto glass in a variety of high-tech applications, including screens and monitors, infrared detectors, high-speed transistors, diodes, and photovoltaics. Indium is present as traces in the Earth's crust, but does not form primary ore deposits, and is currently extracted as a by-product of Zn, Sn and Cu deposits (Werner *et al.*, 2017). The growing use of In in high-tech applications and a restricted supply dependent on only a few present-day producers (*e.g.*, China, Korea, Japan, Canada, Zhang *et al.*, 2015) created challenges to In sourcing worldwide (EU Commission, 2014; Werner *et al.*, 2017).

During the two last decades, mineralogical studies of ore deposits in numerous countries have shown that In is a dispersed element present in various deposit types (Schwartz-Schampera & Herzig, 2002; Schwarz-Schampera, 2014; Werner *et al.*, 2017) and usually shared between several mineral phases (*e.g.*, Pavlova *et al.*, 2015; Andersen *et al.*, 2016; Frenzel *et al.*, 2016; George *et al.*,

2016; Werner *et al.*, 2017). Eighteen In minerals are currently identified, among them, roquesite, petrukite, sakuraiite, indite, laforêtite, dzhalindite (Andersen *et al.*, 2016). In many In-rich deposits, the In minerals are not abundant or even absent. The Kawazu Au–Ag–Cu–Mn–Te epithermal ore deposit in Japan is an exception. Roquesite and dzhalindite are its main ores (Shimizu *et al.*, 2008). In other In-rich deposits, the element is instead substituted in a wide variety of minerals, including base-metal sulfides (Fe-rich sphalerite), copper sulfides (chalcopyrite, bornite), copper-tin sulfides (chalcostannate group, stannite), tin oxides (cassiterite) (*e.g.*, Seifert & Sandmann, 2006; Cook *et al.*, 2011a, b, c; Dill *et al.*, 2013; Pavlova *et al.*, 2015; Andersen *et al.*, 2016; George *et al.*, 2016; Frenzel *et al.*, 2016; Valkama *et al.*, 2016); at this time sphalerite represents about 95% of global In production. The major In-rich deposits are, by decreasing order of importance, sediment-hosted massive sulfides, volcanogenic massive sulfides (VMS), skarn, epithermal, and porphyry; sediment-hosted Pb–Zn and VMS represent more than 60% of In resources (Werner *et al.*, 2017). Magmatic-hydrothermal mineralizations mostly associated with post-collisional magmatic pulses, including skarn-, greisen-, and vein-type mineralization, also represent promising exploration targets for In (SE Finland; Erzgebirge/Krušné Hory; Far East Russia; SW England; South China Tin Belt) (Seifert, 2008; Cook *et al.*, 2011c; Pavlova *et al.*, 2015; Seifert *et al.*, 2015; Andersen *et al.*, 2016; Valkama *et al.*, 2016).

The Variscan Belt contains several ore deposits identified for their significant In resources (Werner *et al.*, 2017), including VMS in Portugal such as Neves Corvo (Pinto *et al.*, 2014) or Lagoa Salgada (Figueiredo *et al.*, 2012), different ore-deposit types in the Erzgebirge, eastern Germany (skarn-type ores in the Pöhla district: Schuppan & Hiller, 2012; Bauer *et al.*, 2017; Jeske & Seifert, 2017), polymetallic Sn(-Ag)-base metal vein- and greisen-type deposits in the old Freiberg, Marienberg, Annaberg, and Ehrenfriederdsdorf-Geyer mining districts (Seifert *et al.*, 1992; Jung & Seifert, 1996; Seifert & Sandmann, 2006; Seifert, 2015) and Sn deposits in SW England (Andersen *et al.*, 2016). According to these recent investigations, late-Variscan granite-related Sn mineralizations might also represent potential interesting In targets.

In this work, we present data available on rare-metal and In distribution in cassiterite and associated minerals of Sn±W ore deposits from Massif Central and Armorican Massif in France, Galicia in Spain and SW England (Table 1; Fig. 1). The role of cassiterite concentrates for the actual world production of In is minor, and the question of whether In can also be hosted in cassiterite remains poorly defined (Pavlova *et al.*, 2015; Andersen *et al.*, 2016). We analysed cassiterite and associated minerals including sulfides and titanium oxides using an electron probe micro-analyzer (EPMA). We paid particular attention to the EPMA analysis method for trace elements in cassiterite related to interferences between Sn and In X-ray emission lines and to a high detection limit described in previous work (Benzaazoua *et al.*, 2003; Pavlova *et al.*, 2015).

Three topics of interest are (1) substitutions of In and other minor and trace elements, such as, Fe, Ti, Nb, Ta and W in the cassiterite lattice, (2) the In distribution among cassiterite and associated minerals, and (3) the trace element content in cassiterite, and more specifically the In content, in terms of ore deposit type.

2. Metallogeny in the Variscan Belt, samples and deposits

The European Variscides, extending from the Iberian Peninsula to Sudetic Mountains, are the result of continental collision between Gondwana and Laurussia. This collision caused the development of a polyphased orogeny, lasting more than 100 Ma from the Early Devonian to the Early Permian, and comprising three major successive stages (*e.g.*, Faure *et al.*, 2009; Maierová *et al.*, 2016) of metallogenesis (Marignac & Cuney, 1999). The first stage of the Variscan orogeny (Early Devonian-Early Carboniferous) corresponds to the closure of Rheic Ocean followed by continental subduction. It is during this stage that sediment-hosted Pb-Zn and VMS were deposited (*e.g.*, Lescuyer *et al.*, 1998; Marignac & Cuney, 1999). The second stage (Mississippian) corresponds to the Variscan continental collision. The third stage of the Variscan Belt (Pennsylvanian to Lower Permian) is a syn- to post-orogenic collapse, marked by normal faults, development of granulite metamorphism of the lower

crust and emplacement of granites (*cf.* Williamson *et al.*, 1996; Seifert, 2008; Simons *et al.*, 2016). Most of the magmatic-hydrothermal rare-metal mineralizations and hydrothermal W, Sn, Sn-F(Li) sulfide mineralizations are associated with the emplacement of peraluminous granites and rare-metal granites of this stage (*e.g.*, Marignac & Cuney, 1999; Bouchot *et al.*, 2005).

Samples of cassiterite-bearing ores were selected from twelve Late Variscan and the only Ordovician granite-hosted Sn mineralizations/deposits in the Armorican Massif and Massif Central (France), in Galicia (NW-Spain), and in SW England (Table 1; Fig. 1). In the French Armorican Massif, Sn±W ore deposits were exploited for Sn (Abbaretz, Saint Renan, La Villeder) and for Sn + W (Montbelleux, Chauris & Marcoux, 1994). The Sn deposits La Villeder and Abbaretz are related to the Variscan leucogranites of the South Armorican zone belonging to the ilmenite serie (Chauris & Marcoux, 1994). Mineralization occurs as quartz – cassiterite ± sulfide veins associated with tourmaline + muscovite + beryl + apatite + albite ± fluorine hydrothermal alteration. At the Sn deposit La Villeder, metre-thick ore veins are hosted by the Lizio leucogranite at its periphery in contact with an Ediacarian metapelitic schist. The density of the ore veins increases toward the contact of the granite with schist. At the Abbaretz Sn deposit, low-angle quartz-veins are associated with the cupola of the Nozay leucogranite in contact with the schist of low metamorphic grade. The Saint Renan Sn deposit is located in the Leon block (Faure *et al.*, 2008), a specific geodynamic domain, where late Hercynian intrusives are polyphased (two-mica potassic granite, locally injected by a leucogranite of probable Permian age). Mineralization occurs as wolframite–quartz veins with minor cassiterite and well-developed meta-granite-greisen ore bodies in the northern part of the Saint Renan Massif (Chauris & Marcoux, 1994). Hydrothermal alteration is essentially represented by tourmalinization and muscovitization. Scheelite (but no cassiterite or wolframite) has been found in the porphyritic granite of the central part and in the fine-grained granite of the southern part. The Montbelleux district is different from the other Sn–W mineralizations by its Ordovician age (Chauris & Marcoux, 1994). Mineralization occurs as quartz–cassiterite–wolframite stockwork in a sodic granite and quartz–wolframite veins in schist near the granite contact (Chauris *et al.*, 1989). The stockwork ore type also contains minor stannite, molybdenite, chalcopyrite, arsenopyrite and sphalerite.

The studied Sn deposits of the French Massif Central are a Cu–Sn–Fe ore deposit (Charrier), W(-Sn) ore deposits (Vaulry, Chataigneraie district) and rare-metal ore deposits disseminated within the rare-metal granites (as defined by Černý *et al.*, 2005) of Beauvoir and Montebbras. Charrier is a complex ore deposit (Picot & Pierrot, 1963), which is composed of: (1) Cu orebodies hosted by Devonian metasediments and metavolcanics in contact with micro-granite; the massive sulfide ores consist of chalcopyrite, and bornite with inclusions of roquesite, sphalerite, wittichenite, tennantite–tetrahedrite; and (2) magnetite–cassiterite–lep-

Table 1. Description of the Sn deposits of the Variscan Belt and the Ordovician Sn deposit of Montbelleux, selected for this study.

Deposit	Resource	Sn total (t) prod. + reserves	Ore type and hostrock	Main mineralogy	Age (Ma)	References
<i>French Armorican Massif, France</i>						
Abbaretz	Sn	2800 + 9100	Qtz-Cst vein-type in schists and some in the Nozay granite	Apy, Py, Ccp, Mo	~315 Ma	(1)

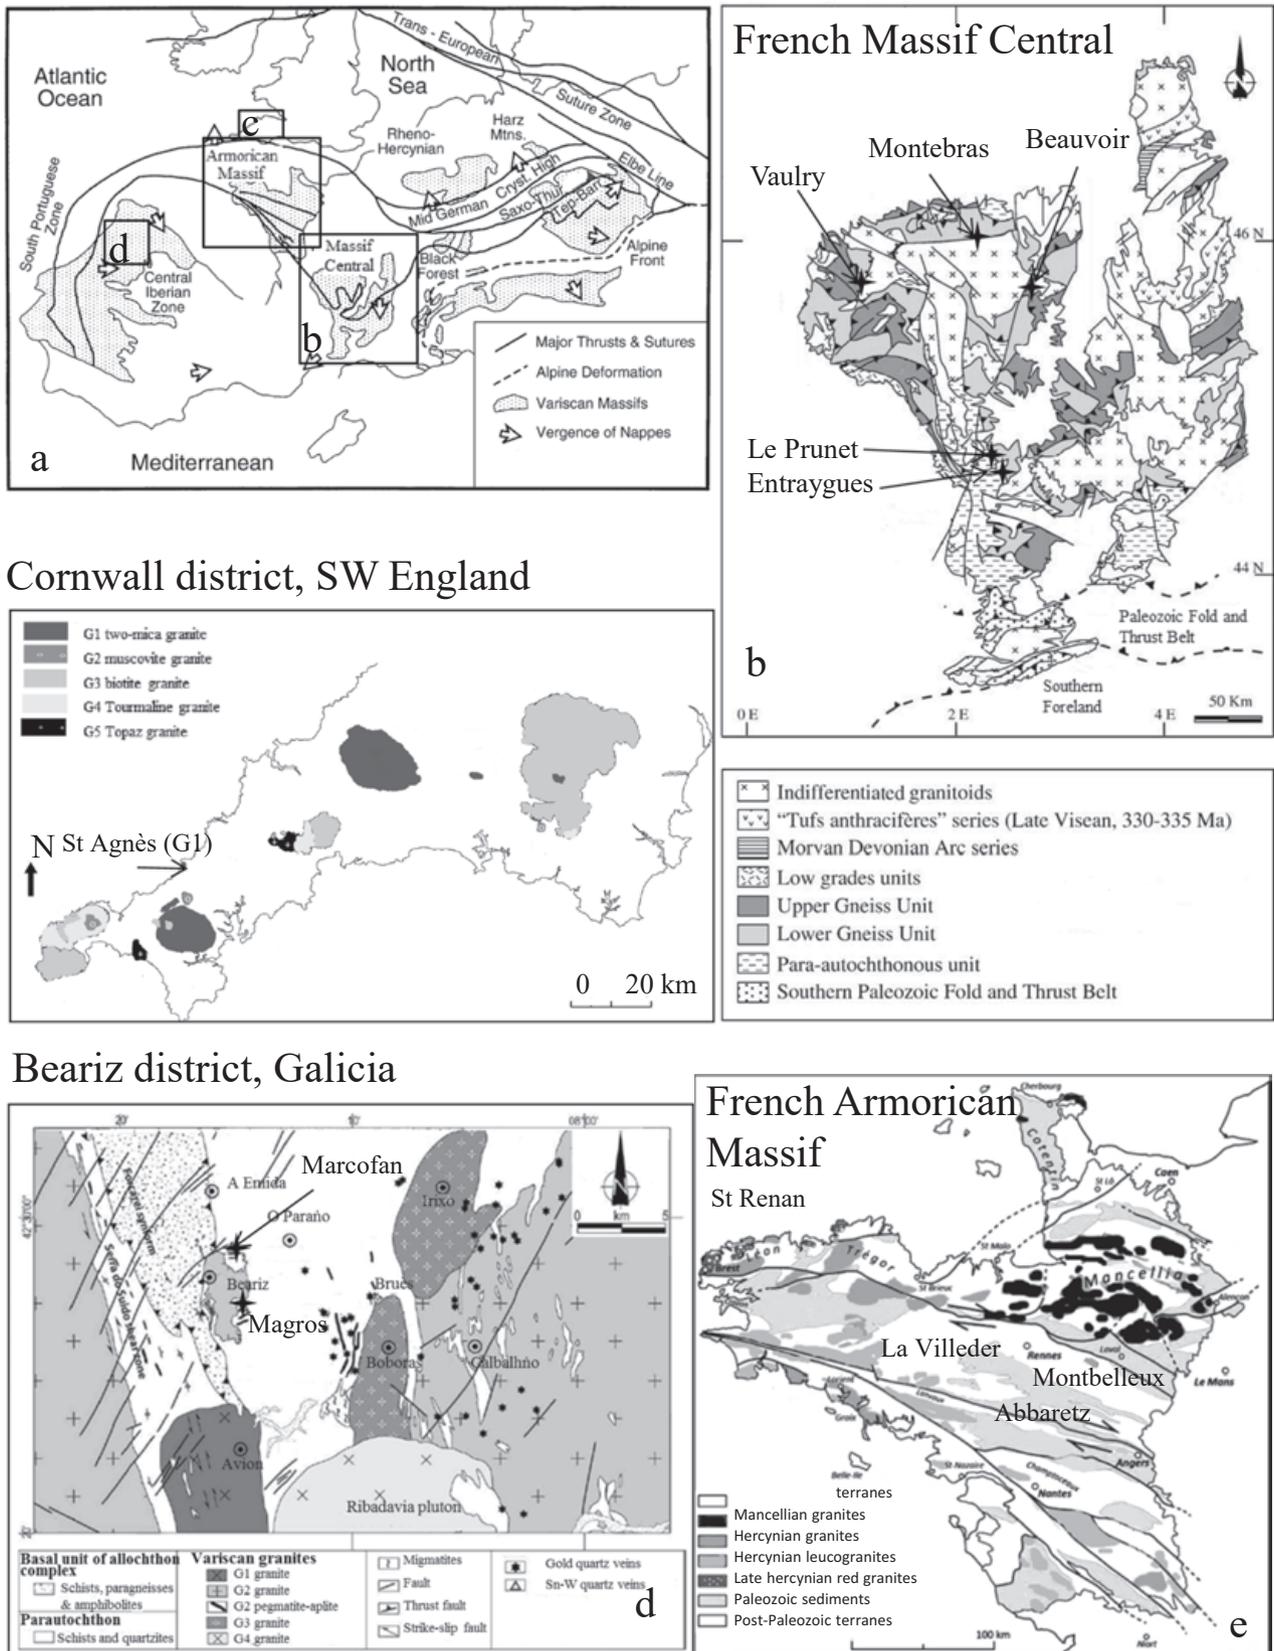

Fig. 1. (a) Schematic map of the Variscan terranes in Europe (after Seifert & Sandmann, 2006); squares indicate the four studied metallogenic provinces. Detailed maps of each province show the distribution of late Hercynian granites and the positions of the studied Sn mineralizations in: (b) French Massif Central (after Melleton *et al.*, 2010), (c) Cornwall district in SW England (after Simons *et al.*, 2016), (d) The Beariz district in Galicia, Spain (after Gloaguen *et al.*, 2014) and (e) French Armorican Massif.

191 idomelane orebodies hosted by metabasalts near the contact
192 with the La Burnolle granite; molybdenite, scheelite,
193 bismuthinite, native bismuth and pyrite are also present.

194 At Vaulry (northwestern Massif Central), the W–(Sn–Cu)
195 mineralization is hosted by the 310 Ma Li–F-rich Blond
196 rare-metal leucogranite close to its contact with Paleozoic
197 schists (Boulandon, 1989). The Vaulry deposit is character-
198 ized by subvertical ore veins, which show three major stages
199 (Vallance *et al.*, 2001): (I) a stage of barren quartz; (II) infill
200 of small fractures by younger quartz, cassiterite and
201 wolframite, and (III) late microcracks infilled with
202 loellingite, chalcopyrite, and pyrite. Stannite, stannoidite,
203 arsenopyrite, bornite with inclusions of roquesite, mawson-
204 ite, scheelite, luzonite and molybdenite were also described
205 (Cantinolle *et al.*, 1985; Boulandon, 1989).

206 The W ± Sn ore deposits of the Chataigneraie district
207 have limited economic potential for W (30 000 t of known
208 WO₃ production distributed across eight deposits; Béziat
209 & Bornuat, 1995), but are not economic for their Sn
210 content. The Sn mineralization is hosted by metamorphic
211 schists in the vicinity of large monzogranites and
212 leucogranitic stocks related to W mineralization at
213 305 Ma (Lerouge *et al.*, 2000, 2005, 2007). It occurs
214 as late magmatic cassiterite in leucogranite stocks
215 (Entraygues leucogranite) and as hydrothermal cassiterite
216 associated with tourmaline, sulfides and rutile, dissemi-
217 nated in biotite–muscovite–chlorite quartz-rich schist (Le
218 Prunet, Entraygues schist). Typically, sulfides essentially
219 consist of chalcopyrite, sphalerite, arsenopyrite and
220 minor pyrite. The magmatic rare-metal (Sn, Ta, Nb,
221 Be, Li) deposits of Beauvoir and Montebas in
222 northwestern Massif Central are economic (Cuney
223 *et al.*, 1992; Raimbault *et al.*, 1995). The Sn mineraliza-
224 tion consists of dominantly disseminated post-magmatic
225 cassiterite associated with a magmatic-hydrothermal
226 paragenesis: lepidolite, topaz, columbo-tantalite, and
227 amblygonite formed at around 570 ± 50 °C (Fouillac &
228 Rossi, 1991). It is hosted by high-phosphorus, peralu-
229 minous small albite–lepidolite granitic stocks emplaced
230 between 317 ± 6 Ma for the Beauvoir granite and
231 314 ± 4 Ma for the Montebas granite (U/Pb columbite-
232 tantalite, Melleton *et al.*, 2015).

233 The Sn-bearing deposits in central Galicia, NW Spain,
234 are of several types, disseminated within LCT pegmatites
235 or in quartz veins associated with granite intrusions in a
236 district where intrusion-related gold deposits also occur
237 (*e.g.*, Gloaguen *et al.*, 2014). Tin–W ore deposits (Mina
238 Vella mine – Marcofán, Mina Soriana mine – Magros)
239 are located on the eastern side of the late-Variscan Beariz
240 granite (Gloaguen, 2006; Sizaret *et al.*, 2009). Minerali-
241 zation occurs in N060°E-trending large normal-faulting
242 quartz veins emplaced both in granite and surrounding
243 micaschist. Large hydrothermal alteration zones occur in
244 micaschist as massive tourmalinite haloes closely related
245 to intrusive bodies and quartz veins. Both cassiterite and
246 wolframite occur in the first mineral assemblage that
247 comprises the infill of quartz veins. Marcofán is essentially
248 hosted by granite, whereas Magros consists of veins
249 hosted by schist.

250 The Saint Agnes Sn–W ore deposit is hosted by a small
251 peraluminous granitic stock associated with the post-
252 Variscan Cornubian Batholith outcropping in SW England
253 (Andersen *et al.*, 2016; Simons *et al.*, 2016). The
254 mineralization consists of quartz–tourmaline–cassiterite–
255 wolframite–chalcopyrite–stannite–sphalerite–löllingite–
256 arsenopyrite veins associated with greisen developed in
257 the apical part of the granitic stock. The greisen alteration
258 minerals include topaz, beryl, apatite and fluorite
259 (Andersen *et al.*, 2016). Textural relationships provide
260 evidence of a high-temperature cassiterite–wolframite ±
261 arsenopyrite–quartz–tourmaline stage followed by arse-
262 nopyrite–chalcopyrite with minor stannite stage (Ander-
263 sen *et al.*, 2016). Roquesite was described in different ore
264 deposits of the Cornwall district (Andersen *et al.*, 2016).

3. Analytical techniques

265 Images in cathodoluminescence have been acquired on a
266 MIRA 3 XMU (TESCAN, Brno, Czech Republic)
267 equipped with a panchromatic cathodoluminescence
268 detector (350–650 nm) (TESCAN BSE/CL detector)
269 under a low vacuum mode (P = 20 Pa nitrogen).
270

271 Analyses of cassiterite and sulfides were performed at
272 the BRGM using a Cameca SX50 EPMA with an
273 accelerating voltage of 20 kV. The spot size was
274 ~1 µm. The system was calibrated with a variety of
275 synthetic oxides and pure elements. Matrix corrections
276 were made with the phi-rho-Z computing program PAP
277 (Pouchou & Pichoir, 1984).

278 Tin and trace elements in cassiterite were analysed with
279 a beam current of 150 nA. Ti–Kα, Sn–Lα, In–Lα/β, Nb–
280 Lα were measured on PET, Fe–Kα on LiF and Ta–Mα/β,
281 W–Lα on TAP. Counting times on peak and background
282 were 10 s for Ti and Fe, and 40 s for other elements.
283 Standards of calibration were natural minerals (cassiterite
284 for Sn, roquesite for In), synthetic oxides (MnTiO₃ for Ti,
285 Fe₂O₃ for Fe), and pure elements (Nb, Ta and W).
286 Detection of In and Ta in cassiterite is complicated because
287 of interference between the Sn X-ray emission lines and
288 those of In and Ta during EPMA-WDS analyses. The
289 major Lα line of In (Fig. S1a and b in Supplementary
290 Material, linked to this article and freely available online at
291 the GSW website of the journal: <http://ejmin.geoscienceworld.org>) and the major Mα line of Ta (Fig. S1d) interfere
292 with the positions of the Lη and the Lα^{2nd order} lines of Sn,
293 respectively. The contributions of the Sn X-rays to In–Lα
294 and Ta–Mα were approximated by analysis of In-free and
295 Ta-free cassiterite and of Sn metal at around 1400 ppm for
296 In and 3000 ppm for Ta. The contribution of the Sn X-ray
297 to the In–Lα is a value similar to that estimated by
298 Benzaazoua *et al.* (2003). To avoid interference with Sn X-
299 rays, In and Ta were measured on the second major In–Lβ
300 and Ta–Mβ even though their intensities are lower than the
301 intensities of the In–Lα and Ta–Mα (Fig. S1c and d). The
302 In–Lβ/In–Lα intensity ratio is 0.45. The detection limits of
303 the elements are (in ppm): 218 (Ti), 369 (Fe), 238 (Sn), 77
304 (Sc), 184 (Ta), 144 (Mn), 253 (In), 208 (W) and 313 (Nb).
305

Elemental mapping of Sn (Sn- $L\alpha$), Ta (Ta- $L\alpha$), Nb (Nb- $L\alpha$), Fe (Fe- $K\alpha$), Ti (Ti- $K\alpha$), and In (In- $L\beta$) in cassiterite were performed on a CAMECA SXFive-FE electron microprobe equipped with a Schottky Field-Emission Gun (FEG) (CAMECA, Gennevilliers – France), using an acceleration voltage of 20 kV and beam current of 200 nA.

Sulfides were analyzed for major and trace elements (S, Cu, Fe, Sn, As, Cd, Zn, In), using a beam current of 20 nA and counting time of 40 s for each element. Standards of calibration were natural minerals (pyrite for Fe, galena for S, sphalerite for Zn, cassiterite for Sn, roquesite for In), synthetic oxides (MnTiO₃ for Ti, Fe₂O₃ for Fe), pure elements (Cu) and AsGa (As). The Cd- $L\alpha$, In- $L\alpha$, S- $K\alpha$ and Sn- $L\alpha$ lines were measured on PET, Cu- $K\alpha$, Fe- $K\alpha$, Zn- $K\alpha$ on LiF, and W- $L\alpha$, As- $L\alpha$ on TAP. The detection limits of the elements were (in ppm): 281 (Cu), 178 (Fe), 494 (Sn), 438 (As), 294 (Cd), 293 (Zn), and 306 (In).

4. Ore-mineral composition

4.1. Cassiterite

Cassiterite grains in seventeen samples of the thirteen Sn ore deposits/occurrences were analysed for In and other trace elements. At least 50 analyses were performed in all the cassiterite samples, except for two samples where cassiterite content was very low (Le Prunet, Marcofán⁶). More analyses were done when In was detected in only small amounts and the amounts of cassiterite allowed it. All data are available in a supplementary electronic file (Table S1) and are presented in summary form with averages and standard deviations in Table 2. Sorting and visual inspection of the data give a good idea of trace element distribution. Averages are low and standard deviations are high compared to averages in most of the cassiterite ores studied because in many analyses, contents were too low to be detected. To provide more representative data, the lowest and highest values, the number of analyses, and the percentage of analyses above the limits of detection are also given. The presence of an element was arbitrarily considered as representative when 20% at least of the analyses were above the limit of the detection. The distribution of Fe, Nb, Ta, Ti and In in cassiterite is highly variable depending on the ore deposit (Fig. 2).

Cassiterite from Saint Agnes is quite pure and only contains traces of Fe and W; it will not be discussed further. Iron is absent or present in small amounts in cassiterite from Beauvoir and Montebbras, Magros and Marcofán. Iron is present in significant concentrations in cassiterite from other mineralizations. Considerable concentrations of Nb are present in cassiterite from Abbaretz (1082 ppm), Montbelleux (3901 ppm), Beauvoir (1764 ppm) and Vaulry (590 ppm), and in two samples from Marcofán (#1: 620 ppm; #13: 880 ppm). Tantalum and Ti are both significant trace elements in cassiterite from all the mineralizations, with Ti contents ranging between 326 ppm (Beauvoir) and 4494 ppm (Entraygues) and Ta contents ranging between 393 (Le Prunet) and 5809 ppm (Montbelleux).

Indium is present in cassiterite from Abbaretz, Montbelleux, and two samples of Marcofán (#1, #13): the highest In content is measured in cassiterite of the Ordovician ore deposit of Montbelleux (average: 519 ± 204 ppm, 91% of analyses above the detection limit, max. In content: 1092 ppm). About 20% of the cassiterite analyses of Marcofán (#13, #11) and Abbaretz are above the In detection limit. Indium is absent or systematically lower than the detection limit in cassiterite from Saint Renan, Beauvoir, Entraygues, Le Prunet and Marcofán (#1, #6). Samples from the Sn deposits La Villeder, Charrier, Montebbras, Vaulry and Magros had less than 16% of analyses above the detection limit. Cathodoluminescence (CL) and elemental mapping of a cassiterite grain from the Montbelleux Sn–W deposit provide evidence of chemical zoning in Ta, Nb, Ti, Fe and a fine zoning in W, which, however, are not related to the In distribution; the darker zones in CL are richer in Fe (Fig. 3).

4.2. Chemical composition of sulfides

A limited number of EPMA analyses were performed on sulphides that are associated with cassiterite in the thin sections from five Sn ore deposits (Table 3). Chalcopyrite, pyrite and sphalerite in the cassiterite–sulfide dissemination of Entraygues show In contents up to 940 ppm, 930 ppm and 520 ppm respectively. Sphalerite is also characterized by a homogeneous Cd content ~5200 ppm. Chalcopyrite and bornite in the Sn-polymetallic deposit of Charrier show average In contents of ~800 ppm and ~430 ppm, respectively. Chalcopyrite, stannite (Cu₂FeSnS₄) and pyrite from the Marcofán Sn deposit have significant In contents (up to 1220 ppm, 620 ppm and 1540 ppm, respectively), whereas sphalerite shows very low In and high Cd (1.5 wt%) contents. Chalcopyrite (up to 450 ppm), arsenopyrite (up to 640 ppm) and pyrite (up to 740 ppm) from the Magros Sn deposit have lower In contents than sulfides from Marcofán. Chalcopyrite and stannite from the Saint Agnes Sn deposit are characterized by high average In contents of 1560 ppm and 2590 ppm, respectively.

5. Discussion

5.1. Incorporation of trace elements in the cassiterite lattice

For further investigations on major substitutions of trace elements in cassiterite, structural formulae were calculated on the basis of six oxygen atoms. The 1:1 correlation between 3-Sn⁴⁺ and Fe³⁺ + In³⁺ + Nb⁵⁺ + Ta⁵⁺ + Ti⁴⁺ (correlation coefficient r^2 of 0.99) shows that mineral stoichiometry is respected. Tin substitutions by Ti, Fe, Nb and Ta are limited in these cassiterites, the number of Sn atoms varying between 2.88 and 2.99. Binary diagrams of Ti, Fe, Nb and Ta atomic contents reported as a function of (3–Sn) show that all the analyses exhibit the same order of incorporation of trace elements in cassiterite for most of

Table 2. EPMA analyses of cassiterite from the different ore deposits. For each trace element average value, standard deviation and the number of analyses are given. The number of analyses is given to estimate detection limit for a set of data. The detection limits are 369 ppm for Fe, 253 ppm for In, 313 ppm for Nb, 184 ppm for Ta and 218 ppm for Ti.

the Sn mineralizations (Fig. S2). The $\text{Sn}^{4+} \leftrightarrow \text{Ti}^{4+}$ substitution is a major one, which can be considered as the easiest substitution due to the similar properties of Sn and Ti cations and similarity between the rutile $[\text{TiO}_2]$ and cassiterite structures. Other Sn^{4+} substitutions by Fe (Fe^{2+} and Fe^{3+}) and rare metals (dominant Ta^{5+} and minor Nb^{5+}) are more complex due to the need to maintain electroneutrality in the crystal. Chemical compositions of cassiterite from different ore occurrences and mining districts are plotted in (Sn, Ti) – (Nb, Ta) – Fe composition diagrams (Fig. 4a–d). Cassiterite from the Sn deposits Beauvoir, Magros and Marcofán, and some cassiterite analyses from the Montbelleux deposit plot along the (Sn, Ti) – (Fe, Mn)(Nb, Ta)₂ join, which defines the $\text{Fe}^{2+} + 2(\text{Nb}, \text{Ta})^{5+} \leftrightarrow 3(\text{Sn}, \text{Ti})^{4+}$ ideal substitution (substitution 1) (Černý *et al.*, 1985; Lerouge *et al.*, 2007). This substitution (1) is also defined in minerals of the tantalite supergroup (Breiter *et al.*, 2005), and micro-inclusions of minerals of the tantalite group have already been observed in cassiterite in Nb–Ta rich systems (Neiva, 2008). That probably implies a limit to Nb, Ta incorporation in cassiterite, which is not well defined to our knowledge. Cassiterite from the Abbaretz Sn deposit and some cassiterite analyses from the Montbelleux Sn deposit plot along the (Sn, Ti) – Fe (Nb, Ta) join,

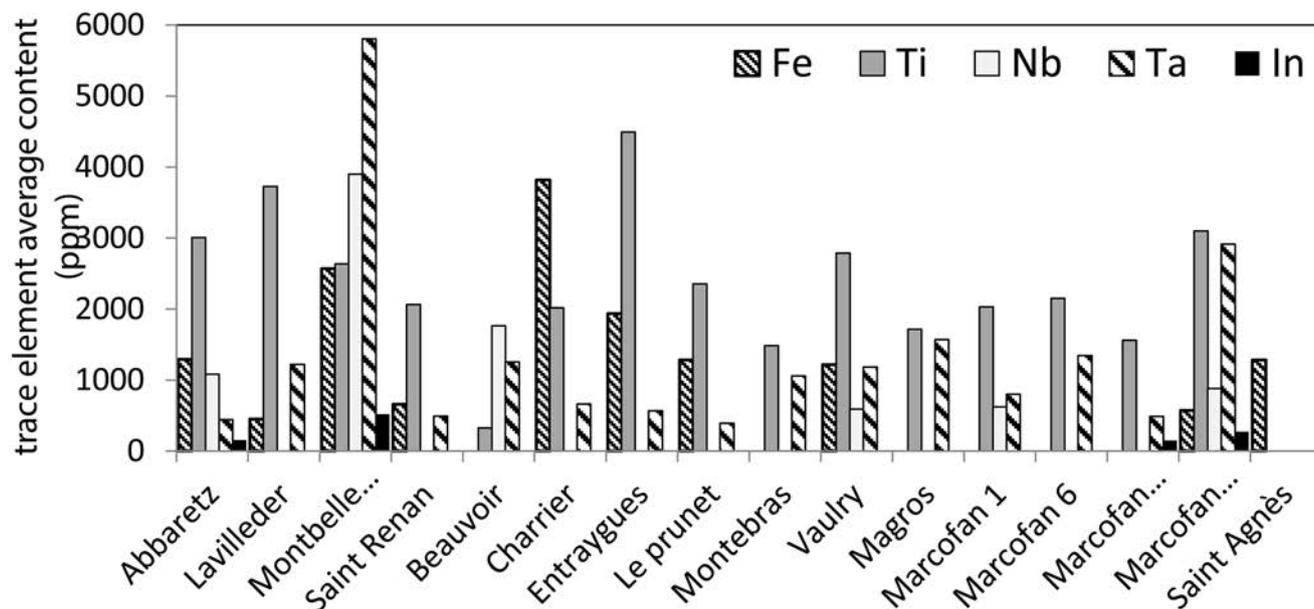

suggesting that incorporation of Fe, Nb, Ta and Ti is rather defined by the $\text{Fe}^{3+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow 2(\text{Sn}, \text{Ti})^{4+}$ substitution (substitution 2). Analyses of the Fe-rich cassiterites of the Sn deposits Charrier, Saint Renan, and Vaulry that plot along the (Sn, Ti) – (Fe, Mn) join might correspond to a $\text{Fe}^{3+} + \text{OH}^- \leftrightarrow \text{Sn}^{4+} + \text{O}^{2-}$ substitution (Möller *et al.*, 1988), but could be due to micrometre-sized inclusions of Fe oxides or ilmenite. Backscattered electron images of cassiterite from these ore deposits did not provide evidence of any inclusions of Fe-bearing phases, favoring the assumption of the substitution.

To conclude, two ideal coupled substitutions (1) $\text{Fe}^{2+} + 2(\text{Nb}, \text{Ta})^{5+} \leftrightarrow 3(\text{Sn}, \text{Ti})^{4+}$, and (2) $\text{Fe}^{3+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow 2(\text{Sn}, \text{Ti})^{4+}$ are at least possible for incorporation of Nb and Ta in the cassiterite studied. That has several implications: (1) incorporation will remain low in Fe-poor cassiterite, (2) incorporation will be limited by the formation of tantalite minerals, and (2) incorporation will highly depend on the Fe valence, and consequently on the redox condition in the system.

In regard to In incorporation in cassiterite, homogeneous spot values and mapping of Montbelleux cassiterite indicate that In is in the cassiterite lattice. Assuming that In is present as In^{3+} in the crust (Smith *et al.*, 1978), and that the electroneutrality of the crystal needs to be maintained,

b.

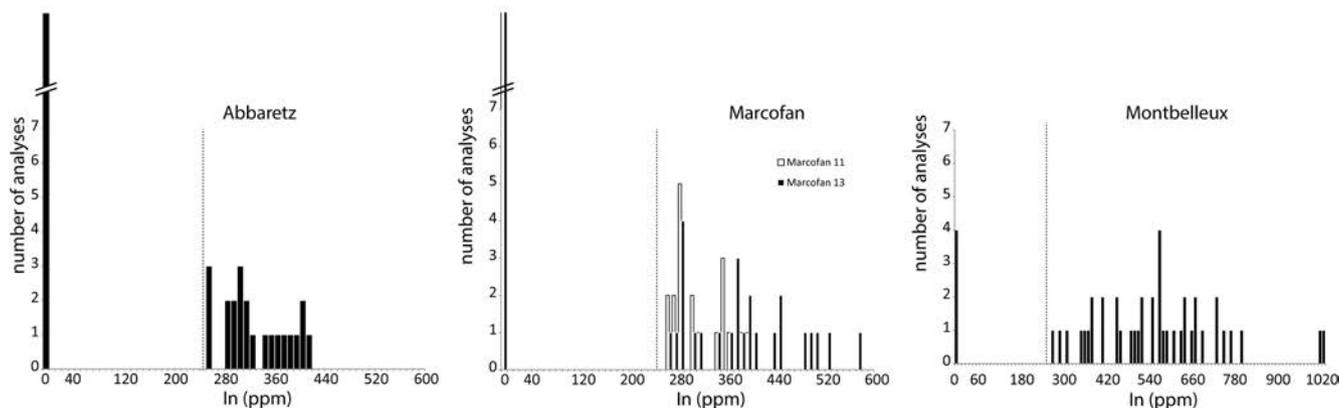

Fig. 2. (a) Histogram showing the average values of Fe, Ti, Nb, Ta and In contents in cassiterite from the thirteen Sn ore deposits; (b) histograms of indium grade distribution (ppm) for some cassiterite from Abbaretz, Marcofán and Montbelleux deposits. Bin size = 10 ppm, EPMA detection limit of 253 ppm is represented by the vertical dotted line on each histogram. The disrupted zero bins represent 78, 78 and 27 analyses for Abbaretz, Marcofán11 and Marcofán13, respectively.

In incorporation may follow the coupled substitution 1: $(\text{Fe}, \text{In})^{3+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow 2 (\text{Sn}, \text{Ti})^{4+}$. Incorporation of In^{3+} in cassiterite via coupled substitution (2) could be possible by modifying the exchange vector as follows: $\text{Fe}^{2+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow \text{In}^{3+} + (\text{Ti}, \text{Sn})^{4+}$.

5.2. Distribution of In in mineral parageneses

Among the studied deposits, the In mineral roquesite is present at the Sn deposits Charrier, Vaulry and Saint Agnes. In these three deposits, cassiterite shows very low In contents. At the Charrier deposit, the order of In distribution in Zn-poor Cu–Sn ore is discrete roquesite, followed by sphalerite (0.8 wt%), chalcopyrite (800 ppm)

and bornite (430 ppm). At Saint Agnes, the In distribution in the studied sample is discrete roquesite followed by stannite (2190 ppm) and chalcopyrite (1565 ppm), in good agreement with Andersen *et al.* (2016).

Cassiterite contains In in only three of the thirteen ore deposits studied: Montbelleux (519 ± 204 ppm), Abbaretz (up to 420 ppm) and Marcofán (up to 580 ppm). Indium contents measured in those cassiterites are consistent with literature data (Briskey, 2005; Pavlova *et al.*, 2015). No sulfides were observed in samples from Montbelleux and Abbaretz. In the Marcofán ore deposit, cassiterite contains In in sulfide-bearing samples (#1: up to 400 ppm, #13: up to 578 ppm); this has already been described by Pavlova *et al.* (2015). The In distribution in

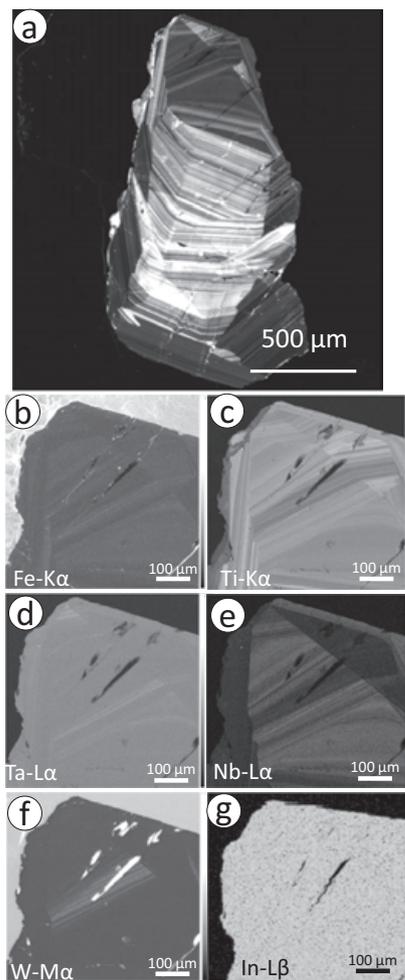

Fig. 3. Mapping of trace elements in cassiterite from the Montbelleux ore deposit. (a) CL image of a single cassiterite grain; (b) to (g) Element mapping of Fe, Ti, Ta, Nb, W and In, using electron microprobe equipped with a Field-Emission Gun (FEG).

Zn-poor Sn–Cu ore of the Marcofán Sn deposit is chalcopyrite (150–730 ppm), followed by cassiterite (150–270 ppm) and stannite (140 ppm).

In other ore samples containing sulfides (Magros and cassiterite–sulfide dissemination of Entraygues), no In mineral is observed and few analyses of cassiterite have detectable In contents, whereas associated sulfides and rutile (when it is analysed) contain In.

The comparative In contents of the different phases from each ore deposit confirm that chalcopyrite, bornite, stannite, pyrite, arsenopyrite, rutile can also contain In. In the studied Sn ore deposits, ores are Zn-poor and Cu-rich, and they are of interest because of the high average In contents in Cu-sulfides: chalcopyrite (up to 2780 ppm); stannite (up to 2670 ppm); bornite (up to 670 ppm).

5.3. Trace element contents in cassiterite and ore deposit type

Mineralizations of the Sn deposits Montebras and Beauvoir consist of magmatic cassiterite disseminated in rare-metal (Sn, Ta, Nb, Be, Li) granites (Černý *et al.*, 2005).

Mineralizations of the other Sn deposits of this study are dominantly hydrothermal vein-type (except the mineralizations of Le Prunet and Entraygues schists, which are disseminated in schists) and spatially associated with late Variscan peraluminous granites. These granites result from partial melting of the crust and fractional crystallisation (Cornwall: Simons *et al.*, 2016; French Armorican Massif: Bernard-Griffiths *et al.*, 1985; Chauris & Marcoux, 1994; Tartèse & Boulvais, 2010; Galicia: Gloaguen, 2006; French Massif Central: Williamson *et al.*, 1996). Partial melting was initiated by increased crustal temperature and by F–Li–P fluids derived from granulite metamorphism of the lower crust in relation with processes of underplating of mantle magmas (*cf.* Williamson *et al.*, 1996; Seifert, 2008; Simons *et al.*, 2016).

Even though Sn hydrothermal mineralizations are spatially associated with granites, they are not systematically genetically linked to them (Marignac & Cuney, 1999; Vallance *et al.*, 2001). Case studies of mineralizations provided evidence of a genetic link between mineralizations and peraluminous granites in La Chataigneraie district French Massif Central (Lerouge *et al.*, 2007), in the Beariz district, Galicia (Gloaguen *et al.*, 2014), in Saint Agnès, SW England (Andersen *et al.*, 2016), and in the South Armorican Massif (Chauris & Marcoux, 1994).

In the Sn deposits studied here, two types of cassiterite may be distinguished according to their trace element (Fe, Ti, Nb, Ta) contents. The first population of cassiterite, which is Fe–Ti-rich and Nb–Ta-poor, mostly corresponds to hydrothermal mineralizations hosted by pelitic schists (Entraygues schists, Le Prunet), metabasalts (Charrier) or granite not genetically linked to mineralizations (Vaulry, Vallance *et al.*, 2001). The second population, which is Nb–Ta-rich, corresponds to magmatic mineralizations disseminated in rare-metal granites (Beauvoir and Montebras) and to hydrothermal vein-type mineralisations genetically associated with peraluminous granites and hosted by both granite and pelitic schists (Marcofán and Magros in the Beariz district, Galicia; Abbaretz and LaVilleder, South Armorican Massif; Ordovician Montbelleux). Reported in a binary Fe vs. Nb+Ta diagram, analyses of hydrothermal Fe–Ti-rich and Nb–Ta-poor cassiterites plot in the field of hydrothermal cassiterite of Tindle & Breaks (1998) (Fig. 4f). Analyses of magmatic-hydrothermal Nb–Ta-rich cassiterites associated with rare-metal granites (Beauvoir, Montebras) plot in the field of rare-element granites and pegmatites of Tindle & Breaks (1998). On the contrary, analyses of hydrothermal Nb–Ta-rich cassiterites from Montbelleux, Marcofán, Magros, Abbaretz and La Villeder plot in the field of rare-element granites and pegmatites, rather than in the hydrothermal field. Thus the field of rare-element granites and pegmatites defined by Tindle & Breaks (1998) is not so restrictive and would rather correspond to cassiterites that show the coupled substitutions (1) $\text{Fe}^{2+} + 2(\text{Nb}, \text{Ta})^{5+} \leftrightarrow 3(\text{Sn}, \text{Ti})^{4+}$ and (2) $\text{Fe}^{3+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow 2(\text{Sn}, \text{Ti})^{4+}$.

It is also noteworthy that the Nb–Ta contents of hydrothermal cassiterites are lower in the Sn deposit La Villeder (granite/schist-hosted) than in the Sn deposit

Abbaretz (schist-hosted), although the Sn mineralizations are considered to be associated with the same types of granite. In the La Chataigneraie district, hydrothermal Fe–Ti-rich and Nb–Ta-poor cassiterites disseminated in schists (Le Prunet, Entraygues) and Nb–Ta-rich magmatic cassiterite in the Entraygues leucogranite derived both from magmatic fluids (Lerouge *et al.*, 2007). These chemical variations of cassiterite from the different granite-related hydrothermal Sn mineralisations probably

reflect the complex processes of Sn-ore deposition, including chemical heterogeneities of the peraluminous magmas (due to, *e.g.*, different degrees of partial melting, fractional crystallisation, different sediment sources), but also interactions of magma-derived fluids with various host-rocks (various compositions, *P–T* conditions) and mixing of magma-derived fluids with external fluids (meteoric, metamorphic) (Lehmann, 1990; Linnen & Cuney, 2005).

On this basis, the Fe vs. Nb+Ta diagram of Tindle & Breaks (1998) could be interesting to efficiently target hydrothermal Nb–Ta-rich cassiterites, which have a favourable chemistry for In incorporation in the cassiterite lattice.

6. Conclusion

The purpose of this work was to evaluate the distribution of In within Sn-polymetallic mineralizations in the western Variscan Belt, to discuss criteria favouring the presence of In within cassiterite, and to determine how In may be substituted. The EPMA analyses of cassiterite from the twelve Variscan Sn-polymetallic ore deposits and from the Ordovician Sn–W ore deposit of Montbelleux provide evidence of low substitution of Sn by Ti, Fe, Nb, Ta and In, highly dependent on ore type, magmatic processes, host rock, fluid/rock interaction processes, and fluid mixing. The highest Ti and Fe substitutions in cassiterite are observed in ores hosted by metapelitic schists. The highest Nb and Ta substitutions in cassiterite are observed in magmatic ores associated with rare-metal granites and in hydrothermal vein-type mineralizations genetically linked with peraluminous granites (Montbelleux, Marcofán and Abbaretz). The significant In content in hydrothermal cassiterites from Montbelleux, Marcofán and Abbaretz correlates with the highest levels of Nb, Ta and Fe substitution, allowing two coupled substitutions to be proposed: (1) $2(\text{Sn}^{4+}, \text{Ti}^{4+}) \leftrightarrow (\text{Fe}^{3+}, \text{In}^{3+}) + (\text{Nb}^{5+}, \text{Ta}^{5+})$ and (2) $\text{Fe}^{2+} + (\text{Nb}, \text{Ta})^{5+} \leftrightarrow \text{In}^{3+} + (\text{Ti}, \text{Sn})^{4+}$, depending on the Fe valency. These substitutions may be limited by the co-formation of tantalite or other Ta-bearing minerals. Further micro-X-ray fluorescence spectrometry coupled with micro-X-ray diffraction and near-edge X-ray absorption fine structure (XANES) measurements at the Fe K-edge could be of major interest to further constrain substitution mechanisms and Fe valency, and the consequence of these substitutions on the cassiterite lattice. In all deposit types, sulfides are the dominant In carriers, notably stannite (up to 3000 ppm In), chalcopyrite (up to 2800 ppm In), pyrite (up to 1490 ppm In), sphalerite (up to 700 ppm In) and arsenopyrite (up to 740 ppm In). Interestingly, other oxides host In, notably rutile (up to 1100 ppm In).

Acknowledgements: Zdenek Johan was a high-level scientist in Mineralogy and Metallogeny, then Research Manager at BRGM for many years (1969–2000). He worked on geological processes associated to the formation of ore deposits, and specially on the metallogenesis of granite-related Sn and W. He published several papers on indium in sphalerite. The first author has had the privilege and the honour to work with him and his wife Věra. She will not forget their kindness and their passion to transmit and share their knowledge to others. This paper is dedicated to them.

This research has been financially supported by the BRGM Research. We would like to thank Michel Outrequin from Cameca (Genevilliers, France) for the FEG mapping. We are grateful to Dr Karen M. Tkaczyk (McMillan

translation) for editing the English text. The Editor in Chief, Professor Reto Gieré, the Guest Associate Editor, Professor Vojtěch Ettler, Professor Thomas Seifert and two anonymous referees are thanked for their constructive comments, which contributed to improvement of the manuscript.
