22 **ABSTRACT**

23 From oxic atmosphere to metallic core, the Earth's components are broadly stratified with

24 respect to oxygen fugacity. A simple picture of reducing oxygen fugacity with depth may be

25 disrupted by the accumulation of oxidised crustal material in the deep lower mantle, entrained

26 there as a result of subduction. While hotspot volcanoes are fed by regions of the mantle likely

27 to have incorporated such recycled material, the oxygen fugacity of erupted hotspot basalts had

28 long been considered comparable to slightly more oxidised than that of mid-ocean ridge basalt

29 (MORB) and more reduced than subduction zone basalts. Here we report measurements of the

30 redox state of glassy crystal-hosted melt inclusions from tephra and quenched lava samples

31 from the Canary and Cape Verde Islands, that we can independently show were entrapped prior

32 to extensive sulfur degassing. We find high ferric iron to total iron ratios ($Fe^{3+}/\sum Fe$) of up to

33 0.27–0.30, indicating that mantle plume primary melts are significantly more oxidised than

34 those at mid-ocean ridges and even subduction zone contexts. These results, together with

35 previous investigations from the Erebus, Hawaiian and Icelandic hotspots, confirm that mantle

36 upwelling provides a return flow from the deep Earth for components of oxidised subducted

37 lithosphere and suggest that highly oxidised material accumulates or is generated in the lower

38 mantle. The oxidation state of the Earth's interior must therefore be highly heterogeneous and

39 potentially locally inversely stratified.

I.   INTRODUCTION

Temperature, pressure, volatile content, major element composition and oxygen fugacity (f_{O2}) are the five parameters controlling the occurrence and extent of partial melting in Earth's mantle, ultimately dictating where magmatic activity occurs on our planet. Of those, variables, oxygen fugacity of the mantle remains the least constrained yet its influence on phase relationship, volatile speciation, element partitioning and mantle physical properties is primary (e.g., Arculus, 1985). In terrestrial rocks, oxygen fugacity varies by over nine orders of magnitude (e.g., Parkinson and Arculus, 1999), but it remains to be seen how much oxygen fugacity varies in the upper mantle, especially in regions where melting occurs and if indeed systematic differences exist between tectonic contexts.

Our understanding of the oxygen fugacity of the upper mantle feeding volcanoes and their magmatic systems has been largely derived from measurements of the oxidation state (expressed as the $Fe^{3+}/\sum Fe$ ratio) of erupted basalts (e.g., Christie et al., 1986; Carmichael, 1991; Bezos and Humler, 2005; Rhodes and Vollinger, 2005; Cottrell and Kelley, 2011). Basaltic lavas sampled at hotspot volcanoes (e.g., Mallmann and O'Neill, 2009; Rhodes and Vollinger, 2005; Roeder et al., 2003) have an oxidation state typically more reduced than basaltic lavas from subduction zone volcanoes and comparable to that of global mid-ocean ridge basalt (MORB), implying that the oxygen fugacity of mantle plumes is similar to that of the mantle feeding MORB, i.e., near the fayalite–magnetite–quartz (FMQ) oxygen buffer (e.g., Bezos and Humler, 2005; Birner et al., 2018; Cottrell and Kelley, 2011; O'Neill et al., 2018; Zhang et al., 2018). However, it has become increasingly clear, from both theoretical considerations (e.g., Anderson and Wright, 1972; Burgisser and Scaillet, 2007; Métrich et al., 2009; Gaillard et al., 2011, 2015) and observations (e.g., Anderson and Wright, 1972;

65   Carmichael and Ghiorso, 1986; Kelley and Cottrell, 2012; Moussallam et al., 2014, 2016; Helz

66   et al., 2017; Brounce et al., 2017; Longpré et al., 2017), that the oxygen fugacity of mantle

67   melts can be strongly affected by the degassing of volatiles (especially sulfur) during magma

68   ascent to the surface. While this effect can be minor for MORB magmas erupted under high

69   hydrostatic pressure (e.g., Shorttle et al., 2015), it may be significant for shallow submarine

70   and subaerial eruptions of hotspot volcanoes. Investigation of the oxygen fugacity of the upper

71   mantle feeding hotspot volcanoes therefore demands identification and study of un-degassed

72   melts that preserve the oxidation state acquired in equilibrium with the mantle.

73

74   In this work, we examine a series of olivine-hosted melt inclusions, embayments and matrix

75   glasses from tephra and lava ballon samples erupted at the hotspots of the Canary (El Hierro

76   and Lanzarote volcanoes) and Cape Verde (Fogo volcano) Islands whose mantle plume origin

77   from the lower mantle is demonstrated from geophysical observations (French and

78   Romanowicz, 2015). Melt inclusions represent samples of the melt taken at various stages

79   during the degassing process, and previous investigations at these volcanoes have highlighted

80   the presence of volatile-rich melt inclusions entrapped at depths exceeding 10 km (Gómez-

81   Ulla, 2018; Longpré et al., 2017) and little affected by sulfur degassing. We report here on

82   measurements of the oxidation state of these melt inclusions obtained by X-ray absorption near-

83   edge structure (XANES) spectroscopy at the iron K-edge.

84

85   Throughout the text, melt fO$_2$ is calculated from Fe^{3+}/$\sum$Fe using Equation 7 from Kress and

86   Carmichael (1991) and ΔFMQ refers to the difference in fO$_2$ between the melt and the Fayalite-

87   Magnetite-Quartz (FMQ) mineral redox buffer as reported in Frost (1991).

88

II. SAMPLES AND METHODS

Olivine-hosted melt inclusions, matrix glasses and embayments from rapidly-quenched tephra and lava balloon samples collected from the 1824 Lanzarote, 2011-2012 El Hierro, as well as tephra samples from Fogo volcano were polished on both sides to obtain doubly-exposed wafers with at least a 10 x 10 µm obstruction-free area through the inclusion. The analysed melt inclusions vary in minimum size from 36 to 181 µm in diameter (Table S1) and consist of brown-coloured transparent glass of ovoid shape (Fig. S1).

Two samples from Fogo volcano eruption were used in this study. The first (Fogo05) was collected on the western part of the Bordeira caldera wall at lat 14.936°; long -24.391°; 2190 m asl and consists of amalgamated tephra (poorly sorted, coarse-ashto fine-lapilli size) with abundant orthopyroxene (up to 15%) and rare olivine phenocrysts. The second (Fogo11) was collected on the western part of the Bordeira caldera wall at lat 14.937°; long -24.392°; 2340 m asl and consists of nearly aphyric (small pyroxenes and very rare olivine) phreatomagmatic tephra (moderately sorted, medium-to-coarse ash size) deposits. Tephra from "Volcan de Tao" (TAO) 1824 eruption at Lanzarote were used in this study (lat 29.03C; long -13.63V). Tephra are highly vesiculated (50–60 vol%), fine to coarse lapilli in size, with olivine phenocrysts ranging from 5 to 10% and trace amounts of clinopyroxene and plagioclase (see details in Gómez-Ulla, 2018). Samples from El Hierro (EH) used in this study came from seawater-quenched lava balloons, with shell ≤5 cm thick collected at lat 27.697°; long -17.993°. The lavas contains olivine, clinopyroxenes and Fe-Ti oxides (see details in Longpré et al., 2017).

2.1 XANES data acquisition

All samples were analysed on Beamline I18 at the Diamond Light Source (DLS) using Fe K-edge XANES (X-ray absorption near-edge structure spectroscopy). The X-rays were focused

115   with Kirkpatrick-Baez mirrors down to 2 µm (horizontal) $\times$ 1.2 µm (vertical) beam size. The

116   beamline utilises a liquid nitrogen-cooled double-crystal monochromator with silicon crystals

117   and the Si (333) reflection was used to increase the energy resolution. Measurements were

118   performed in fluorescence mode, where we used two energy-dispersive Vortex ME-4 silicon

119   drift detectors positioned at 45 degrees to the incident beam (one located directly above the

120   other and pointing towards the sample). The sample was positioned so that the normal to the

121   sample surface was at 45 degrees to the incident X-ray beam. Default analytical conditions for

122   XANES at I18 yield a photon flux of 10^{10} ph/s by attenuating (using a combination of

123   aluminium foils and slit) a 10^{12} ph/s primary beam upstream of the ion chamber. The beam can

124   then be further attenuated (using Al foil). For melt inclusions, the incident X-ray beam was

125   additionally filtered with an Al foil of 0.25 mm thickness to remove the effect of beam damage

126   on the sample (see section below). Matrix glasses, which are water-poor, were analysed using

127   an additional 0.1 mm Al foil attenuation. The energy step sizes and dwell times used are given

128   in Table S2. For melt inclusions, two spectra were acquired and co-added for each analysis.

129   All XANES spectra of melt inclusions were examined for contamination from the olivine host.

130   Spectra showing any structure in the edge and post-edge region were rejected (see Fig. S6 in

131   Moussallam et al., 2014 for an example of contaminated spectra).

132

133   **2.2 Beam damage**

134   The effect of sample exposure to focused beams of X-rays on iron speciation has been

135   investigated in several studies under a range of beam and sample conditions (e.g., Cottrell et

136   al., 2018, 2009; Moussallam et al., 2016, 2014; Shorttle et al., 2015). These works showed that

137   the stronger the photon flux and the more water-rich the sample, the higher the amount of

138   photo-oxidation. Accordingly, we performed a series of tests in order to determine the

139   analytical conditions required to avoid beam damage for our samples.

140

141 We used a hydrated experimental glass of basaltic composition (49.36 wt.% SiO_2, 1.47 wt.%

142 TiO_2, 14.36 wt.% Al_2O_3, 8.61 wt.% FeO, 0.16 wt.% MnO, 9.08 wt.% MgO, 11.71 wt.% CaO,

143 3.26 wt.% Na_2O, 1.3 wt.% K_2O) with a $Fe^{3+}/\sum Fe = 0.22$ (obtained using the Smithsonian basalt

144 glass calibration and Zhang et al., (2018) $Fe^{3+}/\sum Fe$ values from Mössbauer spectroscopy and

145 under the beam damage-free analytical conditions described below). This glass was chosen

146 because it contains 5.2 wt.% H_2O (as determined by SIMS), which is considerably more than

147 any of the natural glasses analysed subsequently, hence it represents a worst-case scenario in

148 terms of beam damage. We positioned the monochromator at a fixed energy of 7114.3 eV,

149 corresponding to the oxidised peak of the pre-edge doublet. We then opened the shutter and

150 counted the fluoresced X-rays every second for 1000 sec (~17 min) (Fig. 1). This beam damage

151 test was popularised by Shorttle et al., (2015) and further used by Cottrell et al., (2018) and has

152 the advantage over the more classic repeated quick-scan approach (e.g., Moussallam et al.,

153 2016, 2014; Wilke et al., 2008) to allow identification of any beam damage occurrence over

154 the first seconds of sample-beam interaction. We found that, under our analytical conditions

155 and using an Al foil of 0.25 mm that attenuates the beam to about 1% of its original flux

156 (calculated based on theoretical absorption, equivalent to ~10^8 photon/s or ~10^7 to 10^8

157 photon/s/µm^2), no change in fluoresced intensity was recorded under beam exposure. By

158 contrast, using a 0.10 mm Al foil or no attenuation at all produced significant photo-oxidation

159 of the iron. These results indicate that Fe in our natural samples, measured using a 0.25 mm Al

160 foil, was not oxidised during XANES analyses. Note that conditions at each synchrotron

161 beamline are slightly different, so the conditions under which we observe no resolvable beam

162 damage at I18 are entirely reproducible but not directly transposable to another

163 synchrotron/beamline. In the same way that calibration with glass standards is required before

164   each XANES analytical session, we recommend that a beam damage test and identification of

165   beam damage-free analytical conditions be performed before each XANES analytical session.

166

167

168   ***Figure 1****: Time series of normalised fluoresced intensity (FF) over I_0 at 7114.3 eV integrated*

169   *over 1 s intervals for a hydrated (5.2 wt.% H_2O) basaltic glass under three different beam*

170   *attenuation conditions. A fresh spot was illuminated with a 2.5 x 1.2 μm^2 beam for each*

171   *analysis. While photo-oxidation can clearly be seen with no beam attenuation and with an*

172   *attenuation down to about 16% of the original beam flux (using a 0.1 mm Al foil), no photo-*

173   *oxidation can be detected once the beam has been attenuated down to 1% of its original flux*

174   *(using a 0.25 mm Al foil). Note that in order to improve the signal/noise level during the test*

175   *with a 0.25 mm Al foil, the detectors were moved closer to the (another time series acquired*

176   *on another spot without the detector adjustment is shown in Fig. S5).*

177

178   **2.3 Standards and Mössbauer spectroscopy**

179   Glass standards for the XANES analyses were prepared in a controlled atmosphere furnace at

180   the Department of Earth Sciences, University of Cambridge using a controlled CO_2-CO gas

181   mixture. For each experiment, 50 mg of sample was placed in a platinum crucible. The sample

182   was then introduced into the furnace and heated at 1400°C and left to equilibrate for two hours.

183   At the end of each experiment, rapid quenching preserved chemical equilibrium as the sample

184   dropped into a container of deionised water. The drop was initiated by short-circuiting the thin

185   platinum wire by passing a current through the thick platinum wires. Six basanite standards of

186   2011-2012 El Hierro magma composition (44.4 wt.% SiO_2, 5.0 wt% TiO_2, 13.7 wt.% Al_2O_3,

187   12.5 wt.% FeO_t, 0.2 wt.% MnO, 8.1 wt.% MgO, 10.7 wt.% CaO, 3.5 wt.% Na_2O, 1.4 wt.%

188   K_2O and 0.5 wt.% P_2O_5) were equilibrated at various fO$_2$ conditions (FMQ–1, FMQ, NNO,

189   NNO+0.5, NNO+1 and NNO+1.5). All experiments were performed twice; first, in order to

190   equilibrate the Pt crucible with Fe at each fO$_2$ (during 24h) and, second, to produce the glass

191   used as standard. All standard glasses were subsequently analysed by electron microprobe. A

192   20-point electron microprobe transect was made across each standard to ensure all samples

193   were homogeneous and that neither iron nor sodium loss had occurred.

194

195   All basanite glass standards were analysed for Fe^{3+}/ΣFe by Mössbauer spectroscopy at the

196   Bayerisches Geoinstitut. Samples were analysed at room temperature using a constant

197   acceleration Mössbauer spectrometer in transmission mode with a nominal 370 MBq [57]Co

198   point source in a 12 µm Rh matrix. The active dimensions of the point source were 500 x 500

199   µm. The velocity scale was calibrated relative to α-Fe and line widths of 0.36 mm/s were

200   obtained for the outer lines of α-Fe at room temperature. Fits to Mössbauer spectra were

201   performed using MossA (Prescher et al., 2012) according to the approach used by Zhang et al.

202   (2018) (xVBF model). A linear baseline was added to account for the shadowing effect and all

fits used the full transmission integral to account for thickness effects of source and absorber

(Rancourt, 1989). Conventional constraints (doublet components with equal widths and areas)

were used and $Fe^{3+}/\Sigma Fe$ ratios were determined from the relative areas corrected for recoil-free

fraction effects according to Zhang et al. (2018). All Mössbauer spectra are shown in Fig. S2

and values are reported in Table S3.

**2.4 XANES spectra processing, $Fe^{3+}/\sum Fe$ calibration and data quality**

As stated above, in order to avoid any beam damage and photo-oxidation of iron under the X-

ray beam, all analyses of melt inclusions were performed using a highly attenuated beam (1%

of initial photon flux). These analytical conditions resulted in acquired spectra of lower quality

than typical for XANES analyses at the Fe K-edge (examples of such spectra are shown in Fig.

2). Noise in the acquired spectra made typical fitting of the pre-edge region with a combination

of a linear function and a damped harmonic oscillator function (DHO), and subsequent centroid

determination (e.g., Wilke et al., 2001; Farges, 2001; Berry et al., 2003; Wilke et al., 2004;

Cottrell et al., 2009; Moussallam et al., 2014) imprecise. To circumvent this problem, we used

the ratio of the pre-edge peak heights, on which we found spectra quality had a lesser effect, to

derive $Fe^{3+}/\sum Fe$ from natural spectra. In detail, the pre-edge region was still fitted with a

combination of a linear function and a damped harmonic oscillator function (DHO) but instead

of determining the centroid we measured the relative height of the $1s \rightarrow 3d$ pre-edge feature

absorption multiplet peaks. The peak height ratio was then parameterised against the Fe valence

state using our basanite glasses standards (Fig. 3).

224

225 ***Figure 2****: Example of edge-step normalised XANES spectra (two co-add) obtained using a 0.25*

226 *mm Al plate attenuation. Spectra from both more oxidised (dashed lines) and more reduced*

227 *(dotted lines) melt inclusions are shown for El Hierro (red), Lanzarote (blue) and Fogo (green)*

228 *volcanoes.*

229

Figure 3: : Calibration line of the peak height ratio determined by XANES compared with the Fe³⁺/∑Fe ratios determined by Mössbauer spectroscopy in basanite standard glasses (this study) and basaltic standard glasses from the Smithsonian (Mössbauer values from Zhang et al., (2018)*). A linear regression through the basanite and basalt standards data (dotted black line) yields an equation of y = 0.37x – 0.09 with an R² of 0.98, a P-value of 1.6x10⁻⁶ and a standard error on the regression of 0.013. Dashed red lines show 95% confidence intervals. Note that the relationship between the peak height ratio and Fe³⁺/∑Fe is well captured by a linear regression for Fe³⁺/∑Fe between 0.1 and 0.4 (see* supplementary Fig. S6)*, in agreement with previous studies (e.g.,* Cottrell et al., 2009*).*

In order to estimate the effect of lower quality spectra on the estimation of the peak height ratio we compared the ratio obtained from the processing of two co-added low quality spectra

243 produced with a 0.25 mm Al plate attenuation to the ratio retrieved from normal high quality

244 spectra obtained with 0.1 mm Al plate attenuation for twelve basaltic Smithsonian standards

245 (Fig. S3). The standard deviation between these analyses was used to determine the error on

246 the peak height ratio ($1\sigma = 0.03$) which translates to a standard deviation of 0.012 on the

247 measured $Fe^{3+}/\sum Fe$ ratio. Note that this is the relative error from XANES analyses, the absolute

248 error in term of $Fe^{3+}/\sum Fe$ is given by the standard error on the calibration curve ($1\sigma = 0.013$).

249 Matrix glasses were acquired with lower attenuation (0.1 mm Al plate) and hence processed

250 using the more commonly used centroid method (e.g., Cottrell et al., 2009; Moussallam et al.,

251 2016, 2014).

252

253 **2.5 Major elements and volatile analyses**

254 Major and volatile (S, Cl, and F) element concentrations were measured on a Cameca SX-100

255 electron microprobe at the Laboratoire Magmas et Volcans, in Clermont-Ferrand using an

256 accelerating voltage of 15 keV, a beam current of 6 nA for major elements and 40 nA for

257 volatiles with a 10 μm spot diameter. Sodium was analysed first to prevent Na loss. The

258 counting time was 10 s for Na, Ca, Ti, P and Si, 20 s for Mg and Al, 30 s for Mn and finally 40

259 s for Fe and K. The instrument was calibrated on natural and synthetic mineral standards and

260 glasses. The Kilauea basaltic glass VG-A99 (Jarosewich et al., 1979) and a pantellerite glass

261 from Eburru Kenya KE12 (Mosbah et al., 1991), which are all international glass standards,

262 were used as an inter-laboratory check for major element, S and Cl and F concentrations,

263 respectively.

264

265 H_2O and CO_2 concentrations were determined by FTIR spectroscopy using a Vertex 70 Bruker

266 spectrometer equipped with an infrared microscope (Hyperion) and an MCT detector at the

267 Laboratoire Magmas et Volcans, in Clermont-Ferrand. Absorption spectra were acquired with

268   128 scans in the near-infrared region at a resolution of 4 cm^{-1}. The total amount of water was

269   calculated from the absorbance of the fundamental OH-stretching vibration at about 3535 cm^{-1}

270   while the amount of CO_2 was calculated using the "carbonate doublet" (Blank and Brooker,

271   1994) at 1515 and 1430 cm^{-1}. The sample thickness was measured on a Raman microscope

272   and background correction (using a cubic function for CO_2 and a linear function for H_2O) was

273   performed using PeakFit software (Jandel Scientific) to measure absorption peak heights. We

274   used molar absorptivity values for basanite from Shishkina et al., (2014). Melt inclusions major

275   and volatile compositions are given in Tables S4 and S5.

276

277   **2.6 Assessment of post-entrapment modification of melt inclusions.**

278   2.6.1   Post-entrapment crystallisation

279   The amount of post-entrapment crystallisation was estimated using the Petrolog3 software

280   (Danyushevsky and Plechov, 2011). Calculations were performed using the olivine-melt model

281   of Danyushevsky, (2001), the density model of Lange and Carmichael, (1990), the model for

282   melt oxidation of Kress and Carmichael, (1988) and the model of Toplis, (2005) for the

283   compositional dependence of the olivine-liquid Fe-Mg exchange coefficient (Kd). Note that

284   calculations in Petrolog3 are performed under anhydrous conditions at 1 atm. Calculations were

285   performed assuming a system closed to oxygen, in which case Fe^{3+} is treated as an incompatible

286   element. The $Fe^{3+}/\sum Fe$ ratios measured by XANES were used to calculate Fe_2O_3 and FeO

287   contents for each melt inclusion as input for the calculations.

288

289   Fig. 4 compares the measured Fo content of the host olivine to its expected value at equilibrium

290   based on uncorrected melt inclusion composition. Most calculated olivine compositions agree

291   with measured compositions within a few Fo% suggesting a limited amount of post-entrapment

292   crystallisation or Fe-loss by re-equilibration. Another method to estimate if iron has been loss

293 from melt inclusions is to compare measured melt inclusion compositions to liquid lines of

294 descent defined by published bulk rocks and glasses at each hotspot locality (Fig. S7). Using

295 this method, we find that melt inclusions from Lanzarote and to a lesser extent, El Hierro, might

296 have suffered some amount of iron loss. We consider this second method to be less accurate,

297 however, as it assumes a co-genetic link between rock sequences that might be unrelated.

298

299

300 *Figure 4: Comparison between measured and equilibrium Fo content of host olivine for melt*

301 *inclusions from Fogo (blue), El Hierro (green) and Lanzarote (red). Equilibrium Fo contents*

302 *are calculated by Petrolog3 software (Danyushevsky and Plechov, 2011) using the model*

303 *of Toplis, (2005) for the compositional dependence of the olivine-liquid Fe-Mg exchange*

304 *coefficient (Kd).*

305

306 Since post-entrapment crystallisation and re-equilibration calculations are highly model

307 dependent and current models of Fe-Mg exchange coefficient are not well calibrated for

308   basanite composition, we choose not to use PEC results from Petrolog3 to "correct" the

309   measured oxidation state of iron in the melt inclusions. We note that the calculated amount of

310   PEC from Petrolog3 is small (from 0 to 3.7%, average of 1.3%, median of 1%) and hence that

311   the measured oxidation states of the melt inclusions are representative of the melt oxidation

312   states at the time of entrapment. Post-entrapment crystallisation corrected compositions are

313   reported in Table S7.

314

315   2.6.2   Volatile diffusion

316   Post-entrapment diffusion of volatiles either through the olivine host (for H) (Hauri, 2002;

317   Massare et al., 2002) or in the vapor bubble (for CO_2) (Anderson and Brown, 1993; Steele-

318   Macinnis et al., 2011) can modify the original volatile content of melt inclusions. As such, our

319   measurements of H_2O and CO_2 can be considered as minimum estimates of the original

320   amounts dissolved in the inclusions even though all of our samples are from rapidly quenched

321   tephra and lava ballons. Higher (than measured) original H_2O and CO_2 contents of the melt

322   inclusions would yield greater calculated entrapment pressures but would make no difference

323   to the conclusions presented here. H diffusion out of a melt inclusion could, however, also have

324   an impact on the oxidation state of the inclusion with a predicted increase of the oxidation state

325   of the melt inclusion with increasing amount of H diffusion (some experiments have shown no

326   effect (Rowe et al., 2007) while others found a complete re-equilibration with the groundmass

327   (Bucholz et al., 2013; Gaetani et al., 2012)). Although this process cannot be ruled out, the

328   opposite correlation between H_2O and oxidation state shown by previous datasets as well as

329   ours (see Results section) strongly argues against this process dominating the observed data

330   variability.

331

332

2.7 Effect of differentiation

Fig. S8 shows an absence of correlation between three proxies of melt differentiation and the oxidation state of the melt, indicating that differentiation is not the dominant factor affecting melt oxidation state in our data set. To assess the potential effect of pre-entrapment crystallization of olivine on $Fe^{3+}/\sum Fe$, we modelled reverse crystallization paths for our melt inclusions along olivine-control lines using PRIMELT3 (Herzberg and Asimow, 2015) until the melts reached equilibrium with Fo_{90} olivine. The results shown in Fig. 5 and Table S8 indicate a modest decrease in $Fe^{3+}/\sum Fe$ with reverse crystallization, demonstrating that melts parental to our melt inclusions were already oxidised.

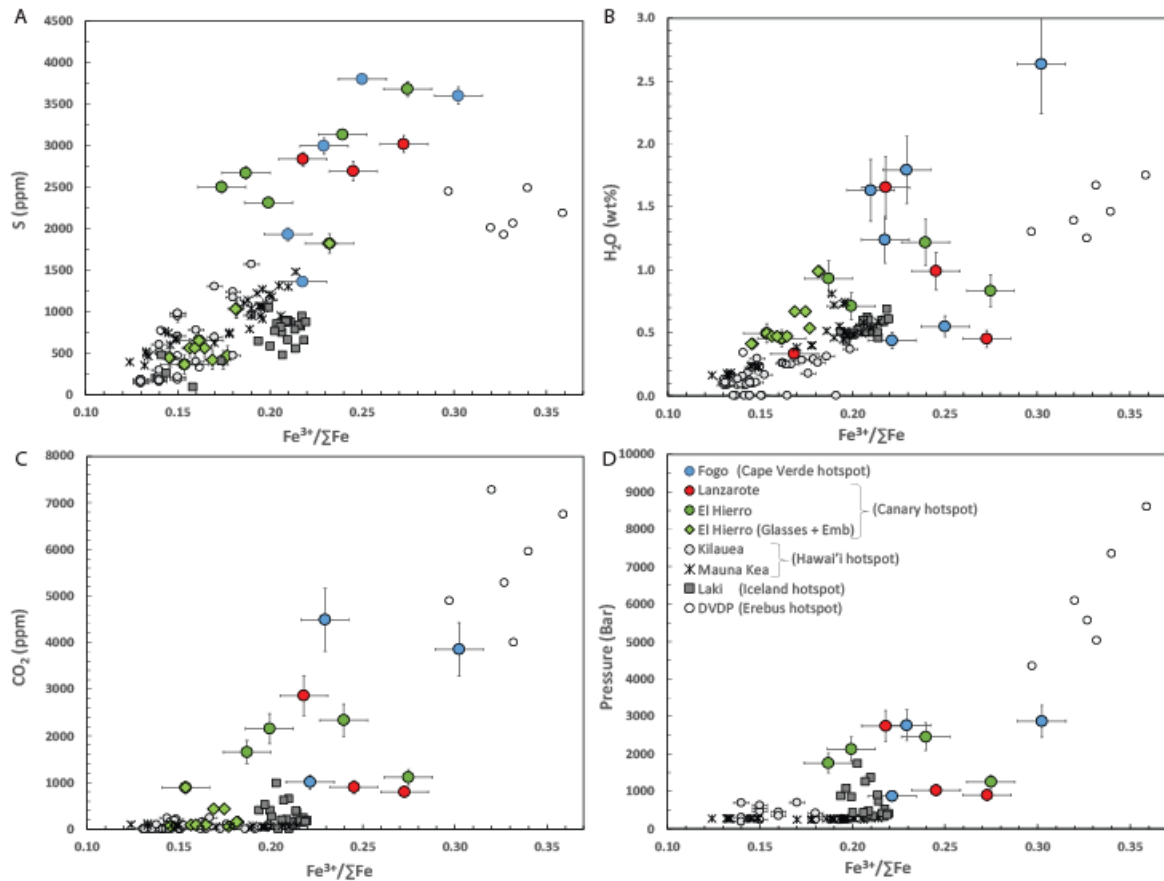

Figure 5: Sensitivity analysis of the effects of post-entrapment crystallisation and pre-entrapment crystallization of olivine on melt $Fe^{3+}/\sum Fe$. Post-entrapment crystallisation estimated using Petrolog3 software (Danyushevsky and Plechov, 2011) assuming a system closed to oxygen, with Fe^{3+} behaving incompatibly, leads to a decrease in $Fe^{3+}/\sum Fe$ in corrected inclusions. The effect of pre-entrapment crystallization of olivine, modelled with PRIMELT3 (Herzberg and Asimow, 2015) *until melt–Fo_{90} olivine equilibrium is reached, is*

shown to have modest effects on $Fe^{3+}/\sum Fe$ over large MgO ranges, suggesting that primary magmas were oxidised. Note that samples from Lanzarote (red) might have experienced Fe-loss (Fig. S9).

III.   RESULTS

Melt inclusions from all three localities have $Fe^{3+}/\sum Fe$ ratios of 0.17 to 0.30 (with one sigma error of 0.012). These values are representative of the oxidation state of the melt at the time of entrapment and of their parental primitive magmas (see calculation of the effect of pre-entrapment processes in the methods section). The $Fe^{3+}/\sum Fe$ ratios of the melt inclusions do not correlate with major element composition (see methods section) but they are strongly correlated with volatile contents (Fig. 6 A to C). More volatile-rich melt inclusions, i.e., those entrapped at greater depths, are systematically more oxidised than their volatile-poor counterparts. This trend is even clearer when comparing our results with reported analyses for the Erebus (Moussallam et al., 2014), Icelandic (Hartley et al., 2017) and Hawaiian (Moussallam et al., 2016; Brounce et al., 2017) hotspots.

Figure 6: Volatile contents of melt inclusions, embayments and matrix glasses and corresponding volatile saturation pressures, for Fogo, Lanzarote and El Hierro (this study) and for Kīlauea (Moussallam et al., 2016), Mauna Kea (Brounce et al., 2017), Laki (Hartley et al., 2017) and Erebus (Moussallam et al., 2014) versus $Fe^{3+}/\Sigma Fe$, determined by XANES. **A**. S concentration (in ppm; determined by electron microprobe). **B**. H_2O concentration (in wt%; determined by Fourier transform infrared spectroscopy). **C**. CO_2 concentration (in ppm; determined by Fourier transform infrared spectroscopy). **D**. Calculated entrapment pressure (using the model of Iacono-Marziano et al., 2012 and accounting for S in the data of this study), with CO_2-H_2O saturation curves shown in the supplementary information. Note that entrapment pressure estimates are always a minimum and that samples from Lanzarote might have experienced Fe-loss.

376   ## IV.   DISCUSSION

377

378   **4.1 A case for oxidised mantle plumes**

379   The most volatile-rich inclusions from El Hierro, Lanzarote and Fogo record $Fe^{3+}/\Sigma Fe$ ratios

380   ranging from 0.27 to 0.30, corresponding to oxygen fugacities around 1.5 to 2 log units above

381   the FMQ buffer. The only available comparable data, from very-deeply entrapped melt

382   inclusions recording conditions prior to extensive degassing, are from Ross Island, Antarctica

383   where similarly high oxygen fugacities have been found (Moussallam et al., 2014). The finding

384   that all investigated hotspot volcanoes (El Hierro, Lanzarote, Fogo and Erebus), for which

385   deeply-entrapped (> 8 km) melt inclusions are available, are associated with strongly oxidised

386   primitive melts suggests a global relationship. This is corroborated by three other lines of

387   evidence: (i) the observation of increasingly-oxidised MORB approaching hotspots such as

388   Iceland (Shorttle et al., 2015); (ii) the abundance of S^{6+} in hotspot basalts (Brounce et al., 2017;

389   Jugo et al., 2010); and (iii) the determination of slightly more oxidizing (up to FMQ+1)

390   conditions in the least-degassed melt inclusions and glasses available from other hotspot

391   volcanoes (Hawai'i (Brounce et al., 2017; Moussallam et al., 2016) and Iceland (Hartley et al.,
392   2017)).

393

394   The most volatile-rich and deeply-entrapped melt inclusions should record conditions closest

395   to the original mantle melt. From our dataset the effect of crystal fractionation on fO$_2$ appears

396   to be minimal (see methods section). Even the most deeply-entrapped inclusions, however,

397   likely experienced some amount of degassing. The original, pre-degassing, degree of oxidation

398   of the melt can be estimated if we know how volatile-rich, especially how sulfur-rich, that melt

399   was prior to degassing. Previous studies for Lanzarote (Gómez-Ulla, 2018) and El Hierro

400   (Longpré et al., 2017) reported melt inclusions with sulfur contents of up to 3900 and 5000

401 ppm, respectively, while for Hawaii (at Lōʻihi) sulfur contents of up to 3300 ppm have been

402 reported (Hauri, 2002). Extrapolating from our dataset, and in coherence with previous

403 degassing models (Moussallam et al., 2014), such sulfur contents would imply a mantle melt

404 oxygen fugacity about 2.0 log units above the FMQ buffer (Fig. 7), hence a mantle source about

405 two log units more oxidised than that feeding mid-ocean ridges (around FMQ; e.g., Berry et

406 al., 2018; Bezos and Humler, 2005; Birner et al., 2018, 2017; Bryndzia and Wood, 1990;

407 Cottrell and Kelley, 2011; Zhang et al., 2018). These estimates are also significantly more

408 oxidised than those inferred for primitive melts in the mantle wedge feeding arc magmas

409 (around FMQ+1; e.g., Bénard et al., 2018; Brandon and Draper, 1996; Parkinson and Arculus,

410 1999).

411

412 It should be noted that by equating the oxidation state of deep melts to that of their mantle

413 source we are assuming that melts are effectively buffered by their mantle source during partial

414 melting. For MORBs, several lines of evidence support this hypothesis; (i) the lack of

415 correlation between $Fe^{3+}/\Sigma Fe$ of MORB glasses and parameters sensitive to the degree of partial

416 melting (Bézos and Humler, 2005, Cottrell and Kelley, 2011), (ii) the similarity in measured

417 oxidation state of MORB glasses and co-located peridotites (Birner et al., 2018), and (iii)

418 experimental investigations of partial melting showing that the melt $Fe^{3+}/\Sigma Fe$ ratios remain

419 constant over varying degrees of partial melting (Sorbadere et al., 2018). In plume contexts it

420 is currently unknown if this assumption remains valid. The relationship between $Fe^{3+}/\Sigma Fe$ and

421 fO_2 in low-degree, volatile- and alkali-rich, partial melts is not well established, and it is

422 conceivable that partial melting in some contexts would operate as an open system favouring

423 the generation of Fe^{3+}-rich melts (Fe^{3+} being mildly incompatible during partial melting, e.g.,

424 Canil et al., 1994; Holloway and Burnham, 1972; Mallmann and O'Neill, 2009; Sorbadere et

425 al., 2018). Given the current lack of evidence of such open-system partial melting processes

taking place, we assume here that partial melting in plume contexts operates similarly to partial

melting in mid-ocean ridge contexts in terms of oxidation state, and hence that the oxidation

state of partial melts pre-degassing is similar to that of their source.

Figure 7: Sulfur contents of melt inclusions, embayments and matrix glasses from this study

and for Kīlauea (Moussallam et al., 2016), Mauna Kea (Brounce et al., 2017), Laki (Hartley et

al., 2017) and Erebus (Moussallam et al., 2014) compared with the oxygen fugacity of the melt

expressed as the deviation from the fayalite–magnetite–quartz buffer. The pink shaded area

represents inferred conditions of the primitive mantle melt feeding hotspots, extrapolated from

the data trend to the maximum reported sulfur contents (of around 3000 to 5000 ppm) in melt

inclusions from hotspot volcanoes. The light orange arrow shows the expected relationship

between sulfur content and melt oxidation state due to sulfur degassing (e.g., Moussallam et

al., 2014, 2016). The dashed grey line shows the maximum amount of sulfur that can be

439   dissolved at a given oxidation state in common basaltic melts at 200 MPa (Botcharnikov et al.,

440   2011). Note that samples from Lanzarote might have experienced Fe-loss.

441

442   **4.2 Recycling of oxidised subducted material**

443   Mantle plumes, as the source of hotspot volcanism, might therefore be considerably more

444   oxidised than their surrounding mantle. The simplest explanation for this phenomenon is that

445   these plumes entrain recycled surface-derived material such as subducted oceanic crust. Indeed,

446   isotopic and trace element evidence indicating the presence of recycled oceanic (and sometimes

447   continental) crust in mantle plumes is abundant (Chauvel et al., 1992; Day et al., 2010; Gómez-

448   Ulla et al., 2017; Hauri, 1996; Hofmann and White, 1982). In particular, helium, argon, lead

449   and strontium isotopic ratios suggest that in both the Canary (e.g., Day and Hilton, 2011;

450   Hiltona et al., 2000)) and Cape Verde (e.g., Christensen et al., 2001; Doucelance et al., 2003;

451   Millet et al., 2008) hotspots a lower mantle and a HIMU component (interpreted as recycled

452   subducted oceanic crust) must have mixed to explain the isotopic composition of extruded

453   lavas. The observation that oxidised mantle melts in hotspot settings are also S-rich (Fig. 7)

454   might additionally suggest the presence of recycled oceanic crust in their parental mantle since

455   hydrothermally-altered crust is enriched in S (Alt et al., 1993), although multiple lines of

456   evidence suggest that most of the S in the subducting slab might migrate to the mantle wedge,

457   with potentially limited amounts being brought deep into the mantle (Bénard et al., 2018; Jégo

458   and Dasgupta, 2014, 2013; Prouteau and Scaillet, 2013; Tomkins and Evans, 2015). An

459   alternative mechanism to explain the oxidised nature of mantle plumes is the decomposition of

460   subducted Fe_2O_3 from banded iron formations to Fe_3O_4 and $Fe_{25}O_{32}$ at pressures above ~60

461   and ~70 GPa, respectively (Bykova et al., 2016). This would generate an oxygen-rich fluid in

462   the lower mantle that could be sampled by ascending plumes. Yet another possibility relies on

463   pressure effects on iron coordination. It has been proposed that pyrite-structured iron oxide

464 (FeO$_2$ – referred to as P-phase) may form under extreme pressure and temperature in the Earth's

465 interior (Hu et al., 2016). If so, highly oxidised patches containing iron in the 3+ valence state

466 may accumulate in the deep lower mantle (Hu et al., 2017, 2016; Streltsov et al., 2017). Early

467 incorporation of such material into mantle plumes would result in decomposition to Fe$_2$O$_3$ and

468 release of O$_2$ during decompression (reaction 1 in Hu et al., 2016), providing an additional

469 mechanism for generation of oxidised hotspot conditions. The hypothesis we favour, the most

470 simple, is the incorporation of recycled surface-derived material in plumes.
471

472   **4.3 Implication for fO$_2$ stratification and partial melting in Earth's mantle**

473 Mantle plumes might therefore play a key role in the deep oxygen – and potentially S – cycles,

474 providing a counterflow to subduction zones, and channelling oxidised material out of the deep

475 Earth. The oxidised nature of mantle plumes might also partly explain their seismic velocity

476 structure. It has been shown that the seismic properties of olivine are highly dependent on iron

477 oxidation state, with olivine containing more Fe^{3+} showing enhanced anelastic relaxation (Ii et

478 al., 2018). The low-velocity anomalies found beneath hotspot volcanoes (e.g., French and

479 Romanowicz, 2015; Zhao, 2007) might then not only indicate elevated mantle temperatures

480 but also raised mantle oxygen fugacity.

481

482 While the geochemically-layered view of the Earth's mantle that prevailed in the twentieth

483 century has been progressively dismantled over the past four decades (e.g., White, 2015), our

484 picture of mantle oxidation state has remained mostly one-dimensional, i.e., fO$_2$ decreasing

485 steadily with depth (Frost and McCammon, 2008; Rohrbach and Schmidt, 2011; Woodland

486 and Koch, 2003). Our findings suggest that geochemical, geophysical and redox

487 heterogeneities should be linked in the Earth's mantle. A heterogeneous mantle in terms of

488 oxidation state implies that processes such as carbon redox melting (the production of

489   carbonated melts from the oxidation of CH_4 or native carbon (Taylor and Green, 1988; Foley,

490   2010; Rohrbach and Schmidt, 2011)) should occur over a wide range of depths in distinct

491   regions of the mantle. Following Stagno et al., (2013), for instance, and considering that the

492   mantle domains feeding hotspots are two log units more oxidised than those beneath mid-ocean

493   ridges, redox melting associated with hotspots should prevail at much greater depths (Fig. 8),

494   especially if these domains are also more carbon-rich.

495

Figure 8: Relationship between depth and oxygen fugacity (expressed as the deviation from the FMQ buffer) for variable $Fe^{3+}/\sum Fe$ from Stagno et al., (2013). The stability fields of diamond and graphite are shown and bounded by the carbonate redox melting reaction line (thick black line). The green arrows (from Stagno et al., (2013)) show the expected evolution of an upwelling mantle with $Fe^{3+}/\sum Fe$ ratio of 0.04, initiating carbonate melting at ~150 km. The blue arrows show the expected evolution of an upwelling mantle with a $Fe^{3+}/\sum Fe$ ratio of

502 0.12, initiating carbonate melting at ~300 km depth. Both scenarios arbitrarily consider mantle

503 sources with 30 ppm carbon (causing a reduction of the bulk rock $Fe^{3+}/\Sigma Fe$ ratio by 1% during

504 redox melting). For greater carbon contents in the mantle sources (likely for hotspot mantle

505 sources), a greater initial $Fe^{3+}/\Sigma Fe$ ratio is required for the oxygen fugacity to remain in the

506 range estimated for MORB and hotspot sources. The relationship between $Fe^{3+}/\Sigma Fe$ ratio and

507 oxygen fugacity for the mantle is calculated from equation 6 of Stagno et al., (2013) and differs

508 from that for the melts (calculated using Kress and Carmichael, (1991)). The boxes for hotspot

509 (this study and Moussallam et al., 2014), subduction zone (SZ) (e.g., Bénard et al., 2018;

510 Brandon and Draper, 1996; Parkinson and Arculus, 1999) and MORB (e.g., Berry et al., 2018;

511 Bezos and Humler, 2005; Christie et al., 1986; Zhang et al., 2018) primitive melts indicate

512 oxidation state only (not depth).

513

V. CONCLUSION

515 We have investigated the redox state of glassy crystal-hosted melt inclusions in lavas of the

516 Canary and Cape Verde Islands by XANES and compared them with similar measurements

517 from Ross Island, Hawaii and Iceland. We showed that, at all five investigated hotspots to date,

518 the apparently reduced state of erupted lavas is primarily acquired from degassing during

519 magma ascent.

520

521 We found that the most deeply entrapped samples, i.e., those preserving mantle equilibrium

522 conditions and found at the Canary, Cape Verde and Erebus hotspots, are highly oxidised. This

523 leads us to infer that globally, present day mantle plumes might be up to two orders of

524 magnitude more oxidised than mantle beneath mid-ocean ridges (that is fO$_2$ two log units above

525 the FMQ buffer) and also more oxidised than the mantle wedge beneath subduction zone

526 volcanoes. What emerges is a novel view of the oxidation state of the mantle, in which large

527 heterogeneities exist both vertically and laterally.

528

529 We further argue that mantle plumes play a key role in the deep oxygen cycle, providing a

530 counterflow to subduction zones by channelling oxidised material out of the deep Earth. This

531 can help to explain why the mean oxidation state of the upper mantle has changed little since

532 the Archean, despite several billion years of subduction of oxidised material. Our findings also

533 have implications for the interpretation of low seismic velocity anomalies beneath hotspot

534 volcanoes, as these might reflect the presence of more oxidised mantle as well as higher mantle

535 temperatures. The more oxidised conditions imply in turn that carbonate redox melting

536 underneath hotspots should take place at much greater depths than underneath mid-ocean

537 ridges.
