27 **Résumé**

28 Des roches contenant de la saphirine ont été décrites dans le Bassin d'Aulus (Ariège, France),
29 au sein d'une zone de contact entre le corps de périclases de Lherz et les métasédiments
30 mésozoïques affectés au Crétacé par un métamorphisme de haute température et de basse
31 pression (Monchoux, 1970, 1972a, b). La saphirine se trouve dans des dépôts clastiques lités
32 caractérisés par une association minérale rare, riche en Al et Mg. Nous présentons ici les
33 résultats de l'étude pétrographique détaillée de seize échantillons représentatifs de la
34 diversité des roches à saphirine de Lherz. Ces brèches et microbrèches sont constituées de
35 clastes monominéraux et polyminéraux de composition variable. Les protolithes de certains
36 de ces clastes sont aisément identifiables : roches ultramafiques, méta-ophites, « cornéennes
37 micacées », socle paléozoïque. Néanmoins, une grande partie des roches à saphirine est
38 composée de débris mono- et polyminéraux dont le ou les protolithes sont inconnus dans la
39 région et restent à identifier. Ces protolithes énigmatiques sont nécessairement composés
40 des minéraux de l'ensemble que nous appelons « assemblage minéralogique à saphirine »
41 (sapphirine-bearing mineral suite : SBMS) et qui comprend les espèces suivantes : saphirine +
42 enstatite + spinelle alumineux + Mg-amphiboles + Ca-amphiboles + kornérupine + minéraux
43 accessoires (apatite, diopside, rutile, serpentine, smectite, tourmaline, vermiculite et mica
44 blanc). Nous mettons en évidence la présence d'inclusions d'anhydrite et d'apatite riche en F,
45 Cl et Sr dans les espèces minérales du SBMS, ainsi qu'une proportion dominante d'éléments
46 clastiques issus du métamorphisme de roches du Keuper dans l'ensemble des échantillons
47 étudiés. La texture bréchique ainsi que la présence de figures sédimentaires dans les roches à
48 saphirine montrent que leur(s) protolithe(s) a (ont) été soumis à un processus de
49 désagrégation mécanique suivi du vannage des clastes en milieu aqueux. Un faible mélange
50 entre les différentes sources est établi par la composition lithologique des roches étudiées.

51 Une étude géochronologique par la méthode U-Pb sur rutile a été réalisée afin d'apporter des
52 contraintes sur l'âge d'une (ou de la) source de ces dépôts clastiques. L'âge obtenu ($98,6 \pm 1,2$
53 Ma) est interprété comme l'âge du métamorphisme de l'assemblage minéralogique à
54 saphirine. Les roches à saphirine ont jusqu'à présent été interprétées comme du matériel
55 crustal modifié en profondeur au contact des roches ultramafiques du corps de Lherz lors de
56 leur remontée vers la surface. Les nouvelles contraintes géologiques apportées par cette
57 étude impliquent : (i) l'origine triasique supérieure à jurassique inférieure du protolith
58 principal des roches à saphirine, (ii) le métamorphisme de ce protolith en présence de
59 saumures le long d'un détachement croûte-manteau actif et chaud au Cénomanien, et (iii) sa
60 bréchification au cours de la remontée du matériel associée au fonctionnement du
61 détachement, suivie du remaniement sédimentaire ultérieur de ce matériel métamorphique.

62

63 **Abstract**

64 Sapphirine-bearing rocks are described in the Aulus Basin (Ariège, France) in a contact zone
65 between the Lherz peridotitic body and Mesozoic metasediments which underwent the
66 Pyrenean Cretaceous high-temperature, low-pressure metamorphic event (Monchoux, 1970,
67 1972a, b). Sapphirine crystals occur in layered clastic deposits characterized by an uncommon
68 suite of Al-Mg-rich minerals. A detailed petrographic study of sixteen samples representative
69 of the diversity of the Lherz sapphirine-bearing rocks is presented.
70 These rocks include breccias and microbreccias with various compositions. Some samples are
71 composed of polymineralic clasts and isolated minerals that derive from regionally well-
72 known protoliths such as ultramafic rocks, meta-ophites, "micaceous hornfels", and very
73 scarce Paleozoic basement rocks. Nevertheless, a large portion of the sapphirine-bearing
74 clastic suite is composed of mono- and polymineralic debris that derive from unknown

75 protolith(s). We define a "sapphirine-bearing mineral suite" (SBMS) composed of
76 monomineralic debris including: sapphirine + enstatite + aluminous spinel + Mg-amphiboles +
77 Ca-amphiboles + kornerupine + accessory minerals (apatite, diopside, rutile, serpentine,
78 smectite, tourmaline, vermiculite and a white mica). We highlight the dominance of
79 metamorphic Keuper clastic materials in the studied rocks and the presence of inclusions of
80 anhydrite and F-, Cl-, Sr-rich apatite in minerals of the Al-Mg-rich suite. The brecciated texture
81 and the presence of unequivocal sedimentary features suggest that the sapphirine-bearing
82 rocks were mechanically disaggregated and then experienced winnowing in underwater
83 conditions with poor mixing between the different sources. We measured U-Pb rutile age
84 data in order to provide constraints on the age of (one of) the protolith(s) of those clastic
85 deposits. The obtained age (98.6 ± 1.2 Ma) is interpreted as the age of metamorphism of this
86 protolith of the SBMS. Previous works interpreted the Lherz sapphirine-bearing rocks as
87 crustal protoliths modified at depth along the contact with the ultramafic rocks of the Lherz
88 body during their ascent towards shallower depths. These new data imply: (i) an Upper
89 Triassic to Lower Jurassic origin for the main protolith of the sapphirine-bearing rocks, (ii) the
90 metamorphism of this protolith along an active hot crust–mantle detachment during
91 Cenomanian times with the involvement of metasomatic, brine-type fluids, and (iii) its
92 brecciation during the exhumation of the material due to the evolution of the detachment,
93 followed by subsequent sedimentary reworking of the metamorphic material.

94

95 I. Introduction

96 Sapphirine ($(\text{Mg},\text{Fe},\text{Al})_8\text{O}_2(\text{Al},\text{Si})_6\text{O}_{18}$; Moore, 1969) is a relatively rare mineral which records
97 either ultrahigh-temperature conditions in silica-rich systems (e.g. Harley & Motoyoshi, 2000,
98 Wheller & Powell, 2014) or high temperature and intermediate pressure conditions in silica-

99 poor systems. In the absence of quartz, sapphirine is described as the product of
100 metamorphic evolution of three main types of protoliths, namely: mafic and ultramafic rocks
101 (e.g. Morishita *et al.*, 2001; Jöns & Schenk, 2008; Feneyrol, 2012), crustal rocks (e.g. Arima &
102 Barnett, 1984), and evaporitic deposits or metasomatic assemblages implying fluids (e.g.
103 Schreyer & Abraham, 1976; Grew, 1988; Harley, 1993; Engvik & Austrheim, 2010). In the
104 Pyrenean belt, Monchoux (1969) first described sapphirine at the northern edge of the Étang
105 de Lherz Iherzolite body, more commonly called the Lherz body (Ariège, France; Fig. 1), in a
106 context involving both ultramafic rocks and metasediments. There, sapphirine crystals occur
107 in layered clastic deposits characterized by uncommon mineral associations including Mg-
108 amphibole, aluminous orthopyroxene, spinel and kornerupine, which is a rare boron-bearing
109 sorosilicate ($Mg_3Al_6(Si,Al,B)_5O_{21}(OH)$; e.g. Grew *et al.*, 1990; Hawthorne *et al.*, 2009). This
110 clastic assemblage consists of polymictic breccias and sandstones exposed in a contact zone
111 between the Iherzolites and Mesozoic metasediments, mainly marbles (Monchoux, 1969).
112 These marbles underwent the high-temperature, low-pressure (HT-LP) Mid-Cretaceous
113 Pyrenean metamorphic event which is recognized all along the North Pyrenean Zone (NPZ;
114 Ravier, 1959; Albarède & Michard-Vitrac, 1978; Montigny *et al.*, 1986; Golberg & Maluski,
115 1988; Dauteuil & Ricou, 1989; Golberg & Leyreloup, 1990; Clerc & Lagabrielle, 2014; Clerc *et*
116 *al.*, 2015; Ducoux, 2017). Golberg & Leyreloup (1990) were the first to ascribe this
117 metamorphic event to a crustal thinning episode in the future NPZ.

118 The Lherz sapphirine-bearing rocks were first interpreted as deriving from lower
119 continental crust lithologies modified at depth along the contact with the ultramafic rocks of
120 the Lherz body during their ascent towards shallower depths (Monchoux, 1970, 1972a). This
121 interpretation needs to be revisited because back then, the processes leading to mantle
122 exposure at the Earth's surface were poorly understood and models of subcontinental mantle

123 exhumation along detachment faults were not yet applied to the Pyrenean case (e.g.
124 Lagabrielle & Bodinier, 2008; Jammes *et al.*, 2009; Duretz *et al.*, 2019). In addition, the North
125 Pyrenean Cretaceous metamorphic event was not recognized as the result of crustal thinning
126 but was thought to be related to the early compressional phases of the Pyrenean orogeny
127 (e.g. Choukroune, 1970; Debrosas, 1978).

128 The occurrence of mantle outcrops in the distal part of passive continental margins is
129 now extensively documented (e.g. Boillot *et al.*, 1980; Espurt *et al.*, 2009; Gillard *et al.*, 2016;
130 Pérön-Pinvidic & Osmundsen, 2016). These recent advances allow for fruitful comparisons
131 between passive margins and some units of the Pyrenean belt and thus provide key
132 arguments to unravel the significance of the geological associations found in the vicinity of
133 mantle exposures in the NPZ (e.g. Masini *et al.*, 2014; Tugend *et al.*, 2015; Corre *et al.*, 2016).

134 In this paper, we present the results of a detailed petrographic study of the formations
135 exposed at the northern border of the Lherz body, in two of the sites where Monchoux (1970,
136 1972a, b) described the sapphirine-bearing rocks. Our aim is to identify the protolith(s) and
137 the geological processes responsible for the formation of such uncommon mineral
138 associations and to explain their juxtaposition with exhumed mantle peridotites.

139

140 II. Geological setting

141 A. The North Pyrenean Zone and the Aulus Basin

142 The Pyrenean belt results from the collision between the Eurasian and Iberian plates
143 that started during the Santonian (e.g. Garrido-Megias, 1972; Olivet, 1996; García-Senz, 2002;
144 Rosenbaum *et al.*, 2002; McClay *et al.*, 2004; Handy *et al.*, 2010). This double-verging orogen
145 is classically divided into three main structural domains: the North and South Pyrenean Zones,
146 composed of Mesozoic and Cenozoic sediments, and the Axial Zone exposing Paleozoic

147 basement rocks. The Axial Zone is separated from the NPZ by the North Pyrenean Fault (NPF)
148 (Fig. 1.1). The NPZ is characterized by a series of inverted basins that opened in the Albian-
149 Cenomanian times and that host about forty different fragments of subcontinental peridotites
150 (e.g. Lacroix, 1894; Bodinier *et al.*, 1987; Fabriès *et al.*, 1991; Henry *et al.*, 1998). These
151 mantle bodies crop out within Mesozoic metasediments that underwent a HT-LP
152 metamorphic evolution that took place between the Albian and Santonian times (110 - 85
153 Ma: Albarède & Michard-Vitrac, 1978; Montigny *et al.*, 1986; Golberg & Maluski, 1988; Clerc
154 *et al.*, 2015). The opening of the NPZ basins occurred in response to the counterclockwise
155 rotation of Iberia, which was accommodated by a sinistral transtensional motion along the
156 future NPF (Olivet, 1996; Sibuet *et al.*, 2007; Gong *et al.*, 2008). The NPZ also includes
157 different isolated Paleozoic North Pyrenean Massifs (NPM) that represent remnants of its
158 original continental basement. These massifs experienced three metamorphic episodes,
159 namely the Hercynian, Permian and Cretaceous events. The Hercynian orogeny (*ca.* 350-300
160 Ma) in the Pyrenees is characterized by a polyphased deformation, accompanied by a HT-LP
161 metamorphism, migmatization and granitic magmatism (e.g. Denèle *et al.*, 2014). During the
162 Permian, the opening of sedimentary basins in the Pyrenees (e.g. Bixel & Lucas, 1987; Lago *et*
163 *al.*, 2004; Saspiturry *et al.*, 2019) induced reheating of the NPM (e.g. Bixel & Lucas, 1987;
164 Briqueu & Innocent, 1993; Lago *et al.*, 2004; Denèle *et al.*, 2012; Asti *et al.*, 2019). Then, the
165 Cretaceous extensional event resulted in an early crustal thinning and in fragmentation of the
166 NPM (e.g. Costa & Maluski, 1988; Vauchez *et al.*, 2013). Evidence for major fluid circulations
167 linked to this last thinning episode was found in some NPM, including talc-enriched faults
168 (Schärer *et al.*, 1999; Boutin *et al.*, 2016) and hydrothermal albitites (Boulvais *et al.*, 2007;
169 Poujol *et al.*, 2010; Fallourd *et al.*, 2014). The Albian-Santonian HT metamorphic event was
170 assigned to the latter crustal thinning episode (Golberg & Leyreloup, 1990) and was further

171 correlated to the exhumation of the subcontinental mantle rocks (Lagabrielle & Bodinier,
172 2008; Clerc & Lagabrielle, 2014). The peak-temperature estimates obtained for the
173 extensional Cretaceous event in the NPZ using Raman spectroscopy of the carbonaceous
174 matter (RSCM) were measured in the Mesozoic metasediments of the Aulus Basin (Fig. 1.2.).
175 Values are grouped around 550°C, reaching 625°C in one sample (Clerc *et al.*, 2015).

176 During the past decade, the North Pyrenean subcontinental peridotite bodies have
177 been repeatedly studied in order to unravel the processes of mantle exhumation in the
178 Cretaceous Pyrenean basins (*e.g.* Lagabrielle & Bodinier, 2008; Jammes *et al.*, 2009; Clerc *et*
179 *al.*, 2012; Clerc & Lagabrielle, 2014; De Saint Blanquat *et al.*, 2016; Lagabrielle *et al.*, 2016;
180 DeFelipe *et al.*, 2017; Lagabrielle *et al.*, 2019). Several recent studies argue for a tectono-
181 sedimentary model for the emplacement of the ultramafic rocks and associated breccias
182 (Lagabrielle & Bodinier, 2008; Lagabrielle *et al.*, 2010, 2016; Clerc *et al.*, 2012; Clerc &
183 Lagabrielle, 2014). In these models, the subcontinental Pyrenean mantle was exhumed along
184 detachment faults and exposed locally on the floor of the narrow NPZ basins during the
185 Cretaceous rifting event, under high thermal conditions.

186 Recent reconstructions based on geological investigations along the NPZ basins led to
187 define a peculiar architecture for the Pyrenean paleo-passive margin controlled by a high
188 thermal regime, thus contrasting with classical models of passive margins exemplified by the
189 Iberia-Newfoundland case (Péron-Pinvidic & Manatschal, 2009). This led Clerc & Lagabrielle
190 (2014) and Clerc *et al.* (2016) to propose a mechanism of rifting in the distal margin domain
191 involving the boudinage of the continental crust under a mobile Mesozoic pre-rift cover
192 detached from the basement along Late Triassic clays and evaporites decoupling layers. A

193 more brittle behaviour characterizes the proximal margin domain. This model was
194 corroborated by recent numerical modelling work (Duretz *et al.*, 2019).

195

196 **B. Geological content and interpretations of the Lherz breccias**

197 The Aulus Basin exposes Mesozoic metasediments and two major ultramafic
198 exposures: the Lherz and Freychinède bodies. Small gabbro and meta-ophite (Late Triassic
199 mafic hypovolcanic rocks) bodies are also found in the vicinity of the ultramafics (Fig. 1.2).
200 Metasediments exposed close to both Lherz and Freychinède bodies are massive carbonates
201 and breccias often referred to as the Lherz breccias (*e.g.* Lacroix, 1894; Choukroune, 1973,
202 1976; Ternet *et al.*, 1997). Previous studies investigated in detail the petrography of the Lherz
203 breccias and discussed their possible modes of emplacement either as {sedimentary breccias
204 (Lacroix, 1892; Choukroune, 1973), tectonic breccias (Lacroix, 1900; Ternet *et al.*, 1997;
205 Debroas *et al.*, 2010, explosion breccias (Avé Lallement, 1968; Minnigh *et al.*, 1980), or
206 tectono-sedimentary breccias (Lagabrielle *et al.*, 2016 and references therein). These studies
207 first pointed to the great variability in the breccia types which range from monomictic
208 carbonate breccias to pure ultramafic breccias. Between these two end-members, polymictic
209 breccias are composed of various proportions of ultramafic and Triassic to Early Cretaceous
210 carbonate clasts (Clerc *et al.*, 2012). The Lherz breccias also contain clasts of meta-ophite,
211 enstatite-gabbro, and minor amounts of Paleozoic crustal rocks.

212 A progressive transition from the peridotite rocks to the surrounding breccias is
213 observed around the Lherz and Freychinède bodies. At an increasing distance from the
214 borders of the ultramafic bodies, one gradually observes: (i) ultramafic breccias with a calcite-
215 rich matrix (ophicalcites; Lagabrielle & Bodinier, 2008; Clerc *et al.*, 2014), (ii) monomictic

216 ultramafic breccias with an ultramafic-rich matrix, (iii) polymictic ultramafic and marble
217 breccias and (iv) monomictic marble breccias (Lacroix, 1894; Monchoux, 1970).

218 The age of deposition of the breccias is a matter of debate because of the lack of
219 stratigraphic or paleontological constraints. The observation of cracks in the peridotite infilled
220 by breccias indicates that deposition of breccias postdates or is synchronous with exhumation
221 of the peridotite to the basin floor (Lagabrielle & Bodinier, 2008). Lherz breccias clasts are
222 dominantly carbonates that underwent metamorphism leading to scapolite and amphibole-
223 bearing foliated marbles. This implies a post-metamorphic or syn-metamorphic origin for the
224 breccias deposition.

225 An anchizonal to epizonal thermal event leading to neoformation of muscovite and
226 paragonite has been characterized in the carbonatic pelitic metasediments of the Turonian-
227 Senonian flysch of the Aulus Basin (80 Ma; Montigny *et al.* 1986). This is confirmed by peak
228 metamorphic temperatures reaching 350°C recently obtained in a tectonic slice of this flysch
229 pinched along the southern rim of the Aulus Basin (Clerc *et al.*, 2015). Dating results obtained
230 in the NPZ show that the thermal anomaly affecting the north Pyrenean basins may have
231 lasted from 107 Ma to 80 Ma, *i.e.* during almost 27 My (see complete references in Clerc *et*
232 *al.*, 2015). This time span is large enough for a succession of events to develop in the
233 sedimentary cover of the Aulus Basin, including: (i) high-temperature metamorphism during
234 the ascent of the peridotites towards shallow levels, (ii) exhumation and disaggregation to the
235 seafloor, followed by sedimentation of the Lherz breccias, (iii) diagenesis and renewed
236 thermal metamorphism following burial under Late Cretaceous flysch sequences.

237 Lagabrielle *et al.* (2016) used the geological constraints summarized above to
238 construct a tectono-sedimentary model for the emplacement of the NPZ peridotites and
239 associated metasediments. This model contrasts with former interpretations of the Lherz

240 body as tectonic slices or olistolith (*e.g.* Vielzeuf & Kornprobst, 1984; Lagabrielle *et al.*, 2010).
241 In their 2016's model, Lagabrielle *et al.* propose that the Lherz peridotite is exhumed along a
242 detachment fault and thus represents the bottom of the Aulus Basin. The Mesozoic
243 sedimentary formations, decoupled from the Palaeozoic basement, are juxtaposed on top of
244 the Lherz body and thereby suffer metamorphism and deformation. Their brecciation and re-
245 sedimentation occurs during their exhumation. This model considers most of the lithologies
246 exposed in the Aulus Basin but it needs refinement since it does not account for the presence
247 of the sapphirine-bearing rocks along the contact with the ultramafic rocks. Following Clerc *et*
248 *al.* (2012) and further studies, the geological setting of the sapphirine-bearing rocks implies to
249 consider this formation as the lowermost levels of the Lherz tectono-sedimentary breccias.
250 Therefore, the sapphirine-bearing rocks are good candidates to represent the first formation
251 emplaced over the detachment fault that allowed the peridotite of the Lherz body to be
252 exhumed towards upper crustal levels and finally exposed on the floor of the former Aulus
253 Basin.

254

255 III. Geological description of sampling sites and analytical methods

256 The sixteen samples of sapphirine-bearing sandstones and breccias studied here were
257 collected at two sites which were first described by P. Monchoux (exposures 1 and 3 in:
258 Monchoux, 1970, 1972a, b), hereafter referred to as sites 1 and 2 (Fig. 1.2 and 2.1). The other
259 exposures described by P. Monchoux, all located along the contact between the Lherz body
260 and the Mesozoic marbles and breccias of the NPZ, have disappeared under the vegetation.

261 At site 1 (42°48'30.52"N 1°22'52.85"E), the sapphirine-bearing sandstones are present
262 along an ancient road-cut, in front of the Etang de Lherz restaurant. The exposure has been
263 cleared on a length of 8 m. The sandstones and breccias form a layered sequence with a

264 rough vertical bedding defined by alternating dark-brown, orange and light-grey layers (Fig.
265 2.1). The thickness of layers varies from some centimetres to one metre and variations in
266 colours are clearly linked to variable lithological compositions. At first sight, the exposure
267 displays four types of clastic layers, namely the A, B, C and D layers (sometimes recurrent)
268 separated by rather sharp contacts (Fig. 2.1, 2.2). (i) Layer A is the dominant type. It
269 corresponds to light grey, coarse sandstones composed of white and grey grains with planar
270 to acicular outlines. Some of the grains show shinning cleavages, evoking micas and
271 amphiboles. Based on HCl tests, some portions of Layer A contain calcite, others do not. (ii)
272 Layer B corresponds to dark-brown layers of ultramafic breccias and microbreccias composed
273 of dominant angular clasts of serpentinized Iherzolite in a sandy matrix with an ultramafic
274 composition. The largest clasts are up to 10 cm long (Fig. 2.2). (iii) Layer C is represented by
275 breccias and sandstones made of dominant ultramafic and minor cm-sized clasts of a
276 granoblastic mafic rock (Fig. 2.3). The latter clasts, which exhibit mm-sized white and black
277 crystals, typically derive from the metamorphism of Triassic ophite (Azambre *et al.*, 1987). (iv)
278 Layer D is a coarse breccia made of a mix of the lithologies forming the previous A, B and C
279 layer types. It is composed of cm- to dm-sized angular clasts of ultramafic rock, white
280 sandstones and microbreccias, and Late Triassic meta-ophites (Fig. 2.4). It also includes clasts
281 of a black rock spotted by white material corresponding to the so-called “micaceous hornfels”
282 (“cornéennes micacées”, Lacroix, 1894) largely exposed some kilometres south of the studied
283 exposures, at Col d’Agnès (Ternet *et al.*, 1997). The “micaceous hornfels” have an unequivocal
284 aspect and are composed of an association of scapolite and phlogopite which derive from the
285 metamorphism of Upper Triassic to Lower Jurassic evaporitic clays during the Cretaceous HT
286 Pyrenean event (93 ± 3 Ma; Ravier & Thiébaut, 1982; Montigny *et al.*, 1986).

287 At site 2 ($42^{\circ}48'26.78''N$ $1^{\circ}23'7.97''E$), located along the north-eastern border of the
288 Lherz body (Fig. 1.2), a portion of the former exposure 3 described by Monchoux (1972a, b)
289 was partly cleared on both sides of a gully, over a few metres between outcrops of the
290 massive peridotite and outcrops of pure marble breccias (Fig. 3.1). The outcrop consists of a
291 pale-green to light-grey microbreccia showing a rough bedding dipping to the south-east.
292 Sandstones layers are interbedded and crossed-stratification can be locally observed (Fig. 3.2,
293 3.3). The microbreccia contains numerous dm-sized angular clasts of variable lithologies
294 including “micaceous hornfels” and poorly serpentinized lherzolites (Fig. 3.4). The ultramafic
295 clasts are more abundant close to the contact with the Lherz body. The entire outcrop is
296 calcite-rich.

297 Although we could not observe the exact exposures described and sampled by
298 Monchoux (1970, 1972a, b), our field observations, even before any microscopic analysis,
299 clearly match his description, in particular (i) the high diversity of the clastic layers
300 components with frequent mixing of light-coloured material and ultramafic material, and (ii)
301 at site 2 a progressive transition from the sapphirine-bearing rocks to the pure marble
302 breccias and microbreccias that dominantly form the overlying Lherz breccia. This transition is
303 depicted by the white dotted line 1 in Figure 3.1.

304 Our sixteen samples allow to recover the diversity of types described by Monchoux
305 (1970, 1972a, b). Eleven samples were collected at site 1 (BCOR 71, BCOR 72, BCOR 73, LHZ
306 49, LHZ 7a, Momo 1, Momo 2, Momo 2a, Momo 2b, Momo 5 and Momo 6). Five samples
307 were collected at site 2 (BCOR 67b, BCOR 68a, BCOR 68b, LHZ 114a and NR 94). Given the
308 thorough mineralogical studies carried out on the same material by Monchoux (1970, 1972a,
309 b) and by Abraham *et al.* (1977), we rather focus on textures, complementary mineral

310 compositions and mineral inclusion patterns that could give clues as to the nature and origin
311 of this uncommon material.

312 Thin sections were prepared for each sample for microscopic observation and electron
313 microprobe (EMP) analyses. The latter were performed in the French Research Institute for
314 Exploitation of the Sea (Ifremer) in Plouzané (Brest, France) using a CAMECA SX100
315 instrument, equipped with five spectrometers and a full set of analysing crystals. Further
316 imaging and analyses in energy-dispersive mode (EDS) were carried out on five samples using
317 a Zeiss Sigma™ field-emission-gun scanning electron microscope equipped with a large-area
318 (50 mm²) EDS silicon drift detector, X-Max Oxford Instruments, at ENS Paris. Raman analyses
319 for phase characterization in sample BCOR 72 were obtained using the Renishaw inVia
320 spectrometer at ENS Paris, with a 514.5 nm argon laser focused through a DMLM Leica
321 microscope. The signal was filtered by edge filters, dispersed by a 1200 or 1800 grooves/mm
322 grating and analysed with a Peltier cooled RENCAM CCD detector, using Si as calibration
323 standard.

324 In addition, laser ablation inductively coupled mass spectrometry (LA-ICP-MS) U-Pb
325 dating was performed on some rutile grains using an ESI NWR193UC Excimer Laser coupled to
326 an Agilent quadripole 7700x ICP-MS available at Géosciences Rennes. Information regarding
327 the analytical procedures can be found in the *Supplementary Material SM1*.

328

329 IV. Results

330 A precise description of each studied sample is provided in the *Supplementary Material SM2*.

331 A. General petrography

332 Three main types of samples can be distinguished on the basis of their mineralogical
333 compositions (Tab. 1, see also Tab. 2):

334 - Type I was collected in coarse breccias of layer D at site 1 and corresponds to portions of
335 polymineralic clasts (Fig. 2);
336 - Type II was collected in layer A at site 1 and at site 2. It corresponds to microbreccias with a
337 calcitic cement and made of either 100% of monomineralic clasts or scarce polymineralic
338 clasts associated with predominant monomineralic clasts;
339 - Type III was collected in layers A, B and C at site 1 and corresponds to microbreccias devoid
340 of any calcitic cement and made of either 100% of monomineralic clasts or of scarce
341 polymineralic clasts associated with predominant monomineralic clasts.

342 Type I samples are very homogeneous (Tab. 2, Fig. 4). Samples BCOR 71, Momo 2 and
343 Momo 6 are made of scapolite (with anorthite, phlogopite, tourmaline and apatite inclusions),
344 phlogopite, diopside, tourmaline and scarce epidote and zoisite. They correspond to clasts of
345 the emblematic Pyrenean “micaceous hornfelses” (Lacroix, 1894), *i.e.* metamorphic Upper
346 Triassic to Lower Jurassic sediments and evaporites. Sample Momo 5 is made of scapolite,
347 diopside, anorthite, phlogopite, potassian hastingsite, tourmaline and calcite and thus
348 corresponds to some intermediate facies between the “micaceous hornfelses” and the
349 surrounding marbles (Ravier & Thiébault, 1982).

350 Type II samples are also rather homogeneous (Fig. 5). Six of the eight samples include
351 sapphirine crystals, and the other two samples include minerals that commonly occur
352 together with sapphirine in our samples (Tab. 2). The complete suite in Type II samples is:
353 sapphirine (with Cl-rich apatite and rutile inclusions), enstatite (with anhydrite, F- and Cl-rich
354 apatite, clinochlore and zircon inclusions), aluminous spinel, Mg-amphiboles (anthophyllite–
355 gedrite solid solution with rutile inclusions), Ca-amphiboles (pargasite with F- and Cl-rich
356 apatite, clinochlore and zircon inclusions; tschermakite), tourmaline, rutile, vermiculite and
357 smectite. The scarce polymineralic clasts are made of sapphirine and Mg-amphibole of the

358 gedrite–anthophyllite series, of sapphirine and aluminous spinel, of anthophyllite and
359 vermiculite, of sapphirine and vermiculite, or of sapphirine, vermiculite and anthophyllite
360 (Tab. 2). A striking feature in these samples is the abundance of kinked vermiculite with open
361 cleavages and ponytail edges (*e.g.* Fig. 5.3). These features suggest that vermiculite derives
362 from the transformation of a former phyllite, likely phlogopite or aspidolite. Monomineralic
363 and polymineralic clasts are all angular, except vermiculite.

364 Type III samples are far more heterogeneous in composition (Tab. 2).

365 - sample BCOR 72 is composed of an accumulation of millimetric to plurimillimetric isolated
366 crystals, dominantly vermiculite and amphiboles with, in order of decreasing abundance:
367 gedrite, pargasite, vermiculite, aluminous enstatite, kornerupine, sapphirine, diopside,
368 tourmaline, rutile and white mica (Tab. 2). Very scarce polymineralic clasts are observed (Fig.
369 6.1). One millimetric kornerupine crystal shows a subhedral shape (Fig. 6.2). A very fine-
370 grained matrix composed of the previously listed minerals and devoid of any calcite can be
371 observed locally.

372 - sample Momo 1 also appears as a friable orange-brown sandstone. It includes angular
373 monomineralic clasts and subangular to rounded polymineralic clasts (Fig. 6.3 and 6.4).
374 Isolated detrital minerals include: magnesio-hornblende, enstatite, chromian hercynite,
375 phlogopite, muscovite, clinopyroxene, quartz, chlorite and several types of plagioclase (An18–
376 58). Polymineralic clasts include: unserpentinized (Fig. 6.4) and serpentinized ultramafic rocks,
377 meta-ophite (Fig. 6.4, Tab. 2), as well as one clast of granitic gneiss. A single clast composed of
378 olivine, plagioclase (An56.9–58.1) and enstatite was also observed. This clast is reminiscent of
379 rocks that are known in the Aulus Basin, namely a Cretaceous alkaline enstatite-gabbro (Les
380 Plagnaux gabbro) (Montigny *et al.*, 1986; Ternet *et al.*, 1997) or the cumulate portion of a
381 Triassic ophitic intrusion (Azambre *et al.*, 1987).

382 - sample LHZ 49 is an orange-brown fine-grained sandstone exclusively made up of angular,
383 submillimetric monomineralic clasts (Fig. 6.5) from a dominant ultramafic protolith. Clasts
384 include: olivine (Fo89.9–91.0), diopside, enstatite, titanian pargasite, hercynite, chromian
385 hercynite, chlorite and minor quartz (Tab. 2).

386 - sample BCOR 73 is a yellowish phyllite-rich sandstone which contains a single centimetric
387 subrounded greenish polymineralic clast (Fig. 6.6). The sandstone is composed of angular
388 monomineralic grains of various nature (in decreasing order of abundance): vermiculite,
389 pargasite, clinopyroxene, scapolite, a green spinel, rutile and tourmaline (Tab. 2). The
390 centimetric greenish subrounded clast derives from a scapolitized amphibolite with
391 clinopyroxene and some vermiculite. This mineral assemblage derives from a micaceous
392 hornfels (Lacroix, 1894; Ravier & Thiébault, 1982), in which primary phlogopite or aspidolite
393 was transformed into vermiculite. This clast is surrounded by vermiculite, oriented roughly
394 parallel to the clast border (Fig. 6.6).

395 **B. Textural analysis**

396 The numerous mineral species that compose the studied samples are all represented
397 by angular and broken monomineralic clasts that obviously derive from a collection of various
398 rock-types (Fig. 4 to 6, Tab. 2). In most cases these clasts are submillimetric fragments of
399 crystals that are disconnected from their original protolith. We also observe larger isolated
400 crystals, millimetric to plurimillimetric in size (centimetric in rare instances, as in samples
401 BCOR 68a and NR 94), of the same species as the submillimetric clasts of the matrix. The
402 largest clasts may be surrounded by submillimetric debris of the same mineral species (Fig. 7).
403 Most of the polymineralic clasts are millimetric to plurimillimetric in size. They are fractured
404 with irregular borders (except in sample Momo 1). In most samples of types II and III which

405 include both monomineralic and polymineralic clasts, the mineral species of the
406 monomineralic clasts are the same as those forming the polymineralic clasts.

407 In seven samples of types II and III, a layering is observable macroscopically (samples
408 Momo 1, Momo 2b and NR 94) or microscopically (samples LHZ 49 and LHZ 7a, BCOR 72 and
409 BCOR 73 (Fig. 8, see also Fig. 6.5). The layers are usually characterized by the accumulation of
410 one or two specific minerals. Representative examples are samples BCOR 72 (Fig. 9) and BCOR
411 73 which both display overabundances of amphiboles and vermiculite. In these cases, the
412 layering is also outlined by the alignment of the planar minerals (in particular vermiculites). In
413 some examples, layering is locally interrupted against polymineralic clasts, the borders of
414 which are coated by planar minerals (*e.g.* sample BCOR 73, Fig. 6.6). In sample Momo 1,
415 layering results from the accumulation of polymineralic clasts of different compositions (Fig.
416 8.2). In addition, each layer may exhibit a grain-size sorting, as also observed in sample NR 94.

417 **C. Definition of the sapphirine-bearing mineral suite (SBMS)**

418 The petrographic study of the sixteen thin sections of sapphirine-bearing rocks reveals
419 that some polymineralic clasts or isolated minerals derive from well-known protoliths such as
420 ultramafic rocks, meta-ophites, micaceous hornfels and, rarely, Paleozoic basement rocks.
421 This is the case for our Type I and part of our Type III, as reported above. Nevertheless, a large
422 portion of the sapphirine-bearing clastic suite is composed of mono- and polymineralic debris
423 that derive from unknown protolith(s). This is the case for Type II and part of Type III samples.
424 The complete mineral suite in these samples is: sapphirine + enstatite + aluminous spinel +
425 Mg-amphiboles + Ca-amphiboles + kornerupine + accessory minerals (apatite, diopside, rutile,
426 serpentine, smectite, tourmaline, vermiculite and a white mica) (Tab. 2). The high recurrence
427 of these minerals found in association with sapphirine in our sample collection leads us to
428 define a "sapphirine-bearing mineral suite", referred to as SBMS.

429 As reported above, most of the clasts observed in the sapphirine-bearing sandstones
430 are monomineralic and isolated. However, rare clasts of polymineralic aggregates exhibiting
431 textural equilibrium are observed in some samples. They are made of sapphirine and Mg-
432 amphibole, of sapphirine and aluminous spinel, of anthophyllite and vermiculite, of sapphirine
433 and vermiculite, or of sapphirine, vermiculite and anthophyllite (Tab. 2). The most frequent
434 associations involve sapphirine and Mg-amphibole of the gedrite–anthophyllite series. These
435 minerals are commonly intergrown, which suggests that they crystallized simultaneously (Fig.
436 5.1, 5.5, 5.6 and 6.1).

437 Finally, we point out that the assemblages represented by the SBMS derive from
438 metamorphic source-rocks that have never been described so far in the Lherz area. In the
439 following, our aim is to characterize these metamorphic source-rocks.

440 D. Mineral chemistry of the SBMS

441 Representative analyses of the main phases forming the SBMS are given in Tab. 3. The
442 chemistry of some minerals of the SBMS uncommonly observed in the region is detailed in
443 the following.

444 - **Sapphirine** occurs in seven samples (Tab. 2, Fig. 5.1, 5.3, 5.5, 5.6, see also Fig. 6.1 and Fig.
445 10.1). In the microbreccias, it appears as up to millimetre-size (LHZ 7a), pale blue to deep blue
446 subhedral crystals, always fractured and commonly corroded. The corrosion gulls are filled by
447 calcite in Type II samples (Fig. 5.3, see also 10.1). Microprobe analyses show that the
448 sapphirine-bearing clasts display high Mg content ($X_{Mg} = Mg/(Mg+Fe_{total}) = 0.91-0.92$), except
449 in LHZ 7a for which X_{Mg} values of 0.83–0.86 may reflect a higher proportion of ferric iron, as
450 suggested by the analysis of spinel. With 1.58(4) Si per formula unit (pfu), sapphirine is close
451 to the classical 7:9:3 (Mg,Fe)O:Al₂O₃:SiO₂ composition (e.g. Podlesskii, 2010). It is nearly
452 devoid of Cr₂O₃ (<0.06 wt%) and NiO (<0.02 wt%).

453 - **Kornerupine** occurs in sample BCOR 72 as a millimetric prismatic subhedral crystal and as
454 fragments with no relationship to each other (Fig. 6.2, see also 10.2). It contains 2.3 wt% B_2O_3
455 according to a wet chemical analysis (Monchoux, 1972a), 3.0 wt% according to EMP analysis
456 in Table 3. It is also characterized by a high X_{Mg} value (0.93) and low Cr_2O_3 (<0.04 wt%) and
457 NiO (<0.08 wt%) contents.

458 - **Aluminous enstatite** occurs as pale blue crystals in three samples (samples LHZ 114a, NR 94,
459 BCOR 72; Tab. 2). It shows a consistent X_{Mg} value of 0.90(1), Al_2O_3 contents from 1.89 to 3.48
460 wt%, with an average of 2.5 wt%, *i.e.* 5 mol% Mg-Tschermak (= $MgAl_2SiO_6$) component. This is
461 among the lowest Al contents in enstatite reported from sapphirine-bearing rocks. The TiO_2 (<
462 0.11 wt%), Na_2O (< 0.19 wt%) and Cr_2O_3 (< 0.5 wt%, mostly <0.3 wt%) contents are not
463 distinctive from enstatite from the Lherz Iherzolite (Le Roux *et al.*, 2007, her corrected Table
464 2), but the low CaO contents are distinctive (< 0.21 wt%, *versus* 0.3 to 1.3 wt% in Iherzolite).

465 - **Aluminous spinel** occurs as blue fragments in mono- or polymimetic clasts (Tab. 2, Fig. 5.4);
466 unlike the clasts of brown or green spinel, it cannot be traced back to common rock-types of
467 the area, either basement or ultramafic bodies. The low Cr_2O_3 (<0.1 wt%) and Fe_2O_3 contents
468 (< 0.05 Fe^{3+} pfu) as well as high Al and high X_{Mg} (> 0.8) are distinctive.

469 The above four mineral species are highly magnesian, as are most of the other species
470 of the SBMS. Indeed, gedrite, anthophyllite, pargasite, vermiculite and tourmaline all have
471 $MgO \pm Al_2O_3 \pm SiO_2$ ($\pm B_2O_3$) as their main constituents (Tab. 3).

472 Sapphirine crystals in samples BCOR 67b, BCOR 68a and BCOR 68b display apatite
473 inclusions (Tab. 2, Fig. 10.1) that are extremely rich in Cl (4.4-4.7 wt%, Tab. 4), close to
474 chlorapatite end-member. Kornerupine crystals bear Cl-rich apatite and anhydrite inclusions
475 (sample BCOR 72; Fig. 10.2). Aluminous enstatite bears inclusions of Cl-rich fluorapatite (1.93
476 wt% Cl and 2.02 wt% F on average) and of Sr-bearing anhydrite (0.42 wt% SrO on average)

477 which may also be associated (Fig. 10.3), and of clinochlore (sample NR 94; Tab. 2 and 4; Fig.
478 10.4). Ca-amphibole crystals also display rare apatite inclusions (sample NR 94).

479 **E. U-Pb dating of rutile in samples BCOR 68a and b**

480 Since the Pyrenees experienced three metamorphic episodes (see section II.A. above),
481 we performed a geochronological study on the only mineral found to be suitable for
482 geochronological dating: rutile (Tab. 2). U-Pb geochronology of rutile was conducted in-
483 context in samples BCOR 68a and b in order to constrain the age of the SBMS. Given their
484 very similar content and sampling location, we consider that these two samples derive from a
485 same (and still unknown) protolith and experienced the same geological processes (Tab. 2).

486 Twenty-six analyses were acquired on ten rutile grains (100 to 200 µm in length)
487 during two analytical sessions (Tab. 5). All analyses were acquired on monomineralic rutile
488 clasts, except three analyses which were performed on a similar rutile inclusion located within
489 a sapphirine crystal clast (S-301018a-1, S-301018a-2, S-301018a-3; BSE images are provided
490 in *Supplementary Material SM3*). Whatever their location, analyses show variable U (58-164
491 ppm) and Pb (1-441 ppm) contents with variable amounts of common Pb ($f_{206}\text{Pb}$ between 0
492 and 2.3%) (Tab. 5). In a Tera-Wasserburg diagram (Fig. 11), they all plot in a concordant to
493 discordant position (depending on the amount of common Pb) and define a well-constrained
494 lower intercept date of 98.6 ± 1.2 Ma (MSWD=1.6). This date is equivalent within error to the
495 ^{207}Pb -corrected date (calculated using Stacey and Kramers (1975) terrestrial Pb evolution
496 model calculated at 100 Ma) of 98.9 ± 0.7 Ma (MSWD=1.4, N=26).

497

498 **V. Discussion: origin of the sapphirine-bearing rocks**

499 **A. Evidence for a tectono-sedimentary origin**

500 The petrological descriptions of the sixteen samples collected at sites 1 and 2 shows
501 that the sapphirine-bearing sandstones and breccia formation is an assemblage of beds of
502 various mineralogical composition and grain size with thicknesses varying from some
503 millimetres to some decimetres.

504 In section IV.B., we describe microbreccia and sandstone samples made of the
505 accumulation of highly fragmented minerals and polymimetic clasts. We show that in most
506 samples, monomineralic clasts exhibit angular shapes, sometimes with little displacement
507 between fragments, and are of the same species as minerals forming the polymimetic clasts.
508 This reinforces the hypothesis of an in-situ disaggregation of the largest clasts to form the
509 submillimetric monomineralic clasts. However, in two samples some monomineralic
510 submillimetric clasts do not have their polymimetic counterpart (*e.g.* quartz in sample Momo
511 1; pargasite, rutile and green spinel in sample BCOR 73), which implies clast mixing at a scale
512 larger than the hand specimen size. Our textural analysis also reveals a layering often defined
513 by the accumulation of one or two specific minerals or polymimetic clasts in seven samples,
514 as well as grain-size sorting at microscopic and macroscopic scales. Those samples which
515 concentrate only few mineralogical species do not correspond to any classical protolith of
516 metamorphic or plutonic origin and can be regarded as placer deposits.

517 These observations collectively imply that the sapphirine-bearing sandstones and
518 breccias accumulated through sedimentary processes in a context of active tectonics allowing
519 for the brecciation of a variety of lithological assemblages. Identifying all the involved
520 lithologies, especially the protolith(s) of the SBMS is thus necessary before any attempt at
521 understanding the geodynamic setting in which those brecciation and mixing processes
522 occurred.

523 **B. Deciphering the sources of the material reworked in the sapphirine-bearing rocks**

524 1- Unequivocal sources

525 Several sources can be unambiguously identified through the mineralogical
526 composition of the studied microbreccia clasts, especially the polymineralic ones. These
527 sources include:

528 (i) Mantle rocks, either fresh or serpentized, as shown by polymineralic clasts including
529 forsterite, serpentine, enstatite, diopside, hercynite or chromian hercynite and by serpentine,
530 hercynite or chromian hercynite isolated crystals;
531 (ii) Upper Triassic to Lower Jurassic meta-ophites (Azambre *et al.*, 1987) as shown by
532 polymineralic clasts including magnesio-hornblende, diopside and plagioclase hosting
533 abundant solid and fluid inclusions, and by isolated plagioclase crystals with the same
534 inclusions;
535 (iii) Upper Triassic to Lower Jurassic deriving "Micaceous hornfelses" (Lacroix, 1894; Ravier &
536 Thiébault, 1982) are identified through polymineralic clasts including scapolite, anorthite,
537 diopside, phlogopite, tourmaline, epidote or apatite and through isolated tourmaline crystals.
538 (iv) Continental basement rocks, represented by one single polymineralic clast made of
539 quartz, phlogopite and muscovite.

540 The conclusion from this first inventory is that, apart from Iherzolites and very scarce
541 basement rocks, the unequivocally identified protoliths that fed the sandstones and breccias
542 derive from an Upper Triassic to Lower Jurassic sequence, which is composed of evaporitic
543 sediments hosting ophites and is affected by the HT-LP Cretaceous metamorphic episode. No
544 protolith containing the complete mineralogy of the SBMS exist in the vicinity of our study
545 zone. The source(s) of the SBMS still have to be identified.

546 3- Source(s) of the SBMS

547 a) Sapphirine-bearing rocks in the Pyrenees: a comparison

548 The present location of the SBMS is the interface between the Lherz exhumed mantle
549 and the Mesozoic marbles and breccias. A comparable situation is encountered for very
550 similar rocks located 40 km East of Lherz, in the Bois de Fajou site (Monchoux, 1970; Fig. 1.1).
551 The latter author also mentioned panning concentrates containing euhedral sapphirine
552 crystals from catchments in the Central Pyrenees, not far from Iherzolite bodies (Fig. 2 in
553 Monchoux, 1972a). This strengthens the idea of considering the sapphirine-bearing rocks as
554 the lowermost levels of the Lherz breccia.

555 In the Pyrenees, sapphirine is also a component of mineral assemblages commonly
556 involved in major contact zones between mantle and crust, formed under granulitic
557 conditions. In that respect, sapphirine-bearing assemblages have been reported from both
558 the Castillon North Pyrenean Massif and in Caussou, only 30 km away from the Lherz body
559 (NPZ, Ariège, France; Fig. 1.1). In the Castillon Massif, sapphirine was described in
560 amphibolites and in corundum-bearing anorthosites that crop out in contact zones between
561 mantle-derived peridotites and crustal kinzigites (Roux, 1977). These sapphirine-bearing
562 amphibolites were interpreted as crustal rocks metamorphosed at the contact with Iherzolites
563 (Vielzeuf & Kornprobst, 1984). In Caussou, rare sapphirine has been reported from
564 amphibole-rich peridotites (Conquére, 1978).

565 The previously referenced settings do not yield proper images of the SBMS because: (i)
566 sapphirine crystals are anhedral in these examples; (ii) no boron-bearing mineral (tourmaline,
567 kornerupine) nor mineral inclusion (Cl- and F- rich apatite, tourmaline, anhydrite) suggesting
568 the involvement of evaporites or evaporitic brines have been observed so far in those
569 assemblages; (iii) the assemblages commonly display coronitic textures, which are not
570 recovered even as relics in the SBMS and (iv) they display different mineral assemblages,
571 notably with mineral components (K-feldspar, quartz...) deriving from the surrounding crustal

572 rocks. Moreover, sapphirine is nearly devoid of Cr₂O₃ (<0.06 wt%) and NiO (<0.02 wt%) in our
573 sample collection, thus showing no direct evidence for mantle contribution. Therefore, none
574 of the assemblages from the Castillon Massif and from the Caussou mantle body is a suitable
575 candidate as source of the SBMS in the Lherz clastic deposits. Even a mix of several selected
576 debris from these different sources will never reconstitute the SBMS. The lack of garnet in the
577 Lherz SBMS is particularly significant in this respect, as well as the lack of quartz and –
578 feldspars debris that would have necessarily been a major contribution to our clastic
579 association since, in the Castillon massif, the rare sapphirine-bearing rocks are hosted by
580 dominant kinzigites. In summary, up to the present day, a suitable protolith for the SBMS is
581 unknown in the entire Pyrenees.

582 **b) Sapphirine-bearing rocks worldwide: the evaporitic signal**

583 Most sapphirine occurrences worldwide are linked to mafic and ultramafic rocks at
584 granulite-facies conditions (*e.g.* Morishita *et al.*, 2001; Jöns & Schenk, 2008; Chetouani *et al.*,
585 2016). However, in several localities, a different type of sapphirine-bearing rocks is described
586 and attributed to metamorphism of either evaporite deposits or of metasomatic assemblages
587 implying fluids of meteoric, evaporitic or hydrothermal origin. An emblematic example is the
588 pelitic whiteschists that occur as layers in talc-bearing series in Sar-e Sang (Afghanistan).
589 There, sapphirine is found together with chlorite, cordierite, corundum, gedrite, kyanite,
590 phlogopite, Na-plagioclase, minor pyrite, quartz, rutile, sillimanite, talc, tourmaline, and
591 xenotime (Schreyer & Abraham, 1976), or with enstatite, forsterite, kornerupine, magnesite,
592 phlogopite and spinel (Grew, 1988). In both cases, the authors interpret these rocks as highly
593 metamorphosed pelitic sediments associated with evaporite deposits. In Ødegarden Verk
594 (southern Norway), sapphirine is described in association with scapolite, Ca-amphibole,
595 clinopyroxene, phlogopite, enstatite, rutile, chlorapatite and talc in scapolitized metagabbros

596 in relation with metasomatism implying brine circulation (Engvik & Austrheim, 2010). In
597 Vestfold Hills (East Antarctica), sapphirine associated with enstatite and spinel is reported in
598 metasomatized, highly magnesian granulites hosted by paragneisses derived from evaporitic
599 mudstones (Harley, 1993).

600 **c) Potential protolith(s) of the SBMS: cataclastic and metasomatized Keuper rocks?**

601 As demonstrated by the microprobe analyses of Table 3, the protolith(s) of the SBMS
602 must be extremely rich in Al_2O_3 and MgO . This is consistent with former bulk-rock analyses by
603 Monchoux (1972a, Tab. 6), even though the analysed rocks are not direct witnesses of their
604 protolith(s) due to their tectono-sedimentary nature. The presence of mineral species such
605 as: (i) boron-bearing kornerupine, (ii) F-, Cl- and Sr-rich apatite, and (iii) anhydrite inclusions in
606 several minerals, points to the involvement of evaporites in producing the peculiar protolith
607 of the Lherz SBMS. It is worth noting that Upper Triassic metasediments are present close to
608 the southern border of the Lherz body, at Col d'Agnès (Ravier & Thiébault, 1982; Ternet *et al.*,
609 1997). These sediments underwent the HT-LP Cretaceous metamorphism and reached
610 temperatures in the range of 550-600°C coeval with mantle exhumation in the Aulus Basin
611 (Clerc *et al.*, 2015).

612 Cataclastic and metasomatized Keuper rocks are commonly found in shear zones
613 related to the major tectonic discontinuities in the NPZ, notably the North Pyrenean Frontal
614 Thrust (NPFT; *e.g.* Betchat and Bonrepaux, Central Pyrenees; Gleizes, 1971; Thiébaut *et al.*,
615 1988, 1992) and the NPF (*e.g.* Larrau-Sainte-Engrâce; Thiébaut *et al.*, 1992). At Betchat and
616 Bonrepaux, a brecciated Late Triassic formation metamorphosed under lower epizonal
617 conditions forms the sole of the NPFT (Gleizes, 1971; Thiébaut *et al.*, 1988, 1992). It is made
618 of gypsum lenses that host dominant magnesian (chlorite, dolomite, pargasite, phlogopite,
619 talc) and aluminous (chlorite, scapolite, phlogopite) minerals, with minor celestite, ilmenite,

620 quartz, sodic plagioclase, rutile and tourmaline (Gleizes, 1971; Thiébaut *et al.*, 1992). This
621 evaporitic material is found in a magnesian chlorite + illite rich matrix that hosts dolomite
622 layers associated with talc and ophite stocks plurihectometric in size. In Arignac-Bedeilhac,
623 north of the NPF, a similar situation is displayed by a Keuper epizonal brecciated formation
624 that again contains (meta-) evaporites (anhydrite and gypsum) and several phases also found
625 in the SBMS, notably: F- and Cl- rich apatite, chlorite, dolomite, magnesian hornblende,
626 phlogopite, rutile, scapolite, talc and tourmaline (Bouscary, 1966; Thiébaut *et al.*, 1988, 1992).
627 The latter authors emphasized the high Mg, Al, Na, Cl, F and B contents of these rocks. In the
628 western Pyrenees, Keuper epizonal cataclastic and metasomatized rocks are also described at
629 the interface between exhumed mantle, felsic continental crustal units and syn-rift Mesozoic
630 sediments in the Urdach and Saraillé massifs (Corre *et al.*, 2018; Lagabrielle *et al.*, 2019). They
631 form a boudinaged layer consisting of a mixture of polymineralic clasts (dolomite,
632 metasomatized felsic metamorphic rocks and micaschists, meta-ophites) embedded within a
633 schistose matrix of talc and Mg-chlorite (Corre *et al.*, 2018; Lagabrielle *et al.*, 2019). A
634 comparable epizonal Keuper formation is also known in the Basque-Cantabrian Basin
635 (DeFelipe *et al.*, 2017).
636 Whether metasomatic alteration was responsible at least for part of the Al-Mg richness in the
637 SBMS prior to or during metamorphism is an open question. Indeed, the involvement of
638 metasomatic fluids is likely, considering reports from the western Pyrenees and the Basque-
639 Cantabrian Basin (Corre *et al.*, 2018; DeFelipe *et al.*, 2017; Salardon *et al.*, 2017; Lagabrielle *et*
640 *al.*, 2019). Derivation of Mg from the metasomatism of Mesozoic dolomitic sediments is
641 unlikely. Indeed, although carbonate formations are frequently dolomitic in the area of HT-LP
642 metamorphism of the NPZ (Fig. 1a), this is considered to reflect metasomatic Mg addition
643 which preceded talc formation. Such Mg addition was achieved through very high fluid-rock

644 ratios, as exemplified by the huge Trimouns talc deposit (Boulvais *et al.*, 2006; Boutin *et al.*,
645 2016). Accordingly, the other possible source of Mg is the Keuper brines themselves.

646 All the geological markers around the Lherz sapphirine clastic deposits indicate that
647 they reside at the location of a major detachment capping the exhumed mantle. Accordingly,
648 we may assume that the original protolith(s) of the Lherz SBMS evolved in a detachment fault,
649 assisted by variable amount of fluids containing elements including Si, Mg, Fe, Ca, Cl, B, Sr, F.
650 Transformation of Triassic material along major detachment faults has already been
651 emphasized by Corre *et al.* (2018). The latter authors describe tectonic contacts between
652 mantle rocks and Mesozoic sediments characterized by the occurrence of Triassic cataclastic
653 material affected by intense syn-kinematic hydrothermal circulations. These contacts
654 represent the detachment faults along which subcontinental mantle was exhumed toward
655 upper crustal levels during the opening of the Albian-Cenomanian rift at the locus of the
656 future NPZ.

657 **4- P-T formation conditions of the Lherz SBMS protolith(s)**

658 Calculating P and T formation conditions from the SBMS is problematic since: (i) the
659 SBMS, owing to its tectono-sedimentary nature, might derive either from a single protolith or
660 from a mixture of several protoliths; (ii) even in the case of a single protolith, the sapphirine-
661 bearing clasts are too small to identify the entire primary paragenesis and the whole-rock
662 chemistry that are needed for multi-equilibrium thermobarometry; (iii) thermodynamic data
663 for sapphirine remain highly uncertain (*cf.* Podlesskii *et al.*, 2008; Wheller & Powell, 2014); (iv)
664 a contribution of evaporite-derived fluids is likely thus making the P-T calculation highly
665 dependent on reduced H₂O activity (Nijland *et al.*, 1998; Engvik & Austrheim, 2010).
666 Consequently, we will only attempt to fix bounds to the P-T estimates.

667 In the absence of corundum (or pyrope), a lower T limit is given by the extent of
668 Tschermak substitution in orthopyroxene, through the fluid-independent reaction enstatite +
669 corundum = $MgAl_2SiO_6$ ('Mg-Tschermak'). The 5-6 mol% Mg-Tschermak measured in
670 aluminous enstatite indicate a *minimum* T of about 550°C at low pressures and of ~600°C at
671 1.5 GPa (e.g. Gasparik, 1994), regardless of fluid presence or composition.

672 Another fluid-independent indication is given by the stability of anthophyllite (vs. talc +
673 enstatite in the $MgO-SiO_2-H_2O$ system), which implies a *minimum* T varying from ~550 °C at
674 very low pressure to ~750°C at 1 GPa (Berman *et al.*, 1986).

675 According to the inclusion and intergrowth relationships observed in the clasts, the
676 pairs enstatite–chlorite, sapphirine–anthophyllite and sapphirine–spinel were stable in the
677 source rock of the SBMS (Tab. 2, see also Fig. 5.1, 5.5, 5.6, 6.1 and 10.4). In the magnesian
678 system, the stability of sapphirine (+ H_2O) combined with those of chlorite + enstatite and of
679 anthophyllite define a relatively narrow crescent in the P-T field, about 50°C wide in its
680 broadest part, concave toward the P axis and extending from about 600°C at very low P to
681 about 800°C near 1 GPa P_{H_2O} (Seifert, 1974; Berman *et al.*, 1986). However, all the reactions
682 involved are dehydration reactions and so the whole crescent may shift to lower
683 temperatures with decreasing H_2O activity.

684 Leaving aside the ultrahigh-temperature assemblages like sapphirine–quartz or spinel–
685 quartz (e.g. Wheller & Powell, 2014), crystallization of sapphirine-bearing assemblages in
686 silica-poor systems most commonly indicates facies conditions of amphibolite–granulite
687 boundary to granulitic, with temperatures ranging from 700°C to 900°C and pressures from
688 0.3 to 1.1 GPa (e.g. Ackermann *et al.*, 1982; Windley *et al.*, 1984; Christy, 1989; Vry &
689 Cartwright, 1994). For the closest natural assemblages to the SBMS found in the literature,
690 the P-T estimates are around 700 - 800°C and 0.35 - 1.0 GPa (Ackermann *et al.*, 1982; Vry &

691 Cartwright, 1994). One should however bear in mind that, (i) in the magnesian system, from
692 about 0.03 to at least 0.7 GPa P_{H_2O} , sapphirine (+ H_2O) may form from chlorite + spinel +
693 corundum at temperatures between 600° and 750°C, depending on pressure (Seifert, 1974),
694 (ii) at any given pressure, chlorite dehydrates at a less than 50°C higher T than sapphirine
695 formation (Seifert, 1974), and (iii) in the presence of brines and/or lowered H_2O activity,
696 dehydration reactions (the sapphirine-forming ones in particular) occur at lower
697 temperatures, by as much as 120°C lower for H_2O activity reduced to 0.4 (e.g. Simon &
698 Chopin, 2001). Accordingly, and given the abundance of vermiculites which likely derive from
699 phlogopite or aspidolite, the best T estimate range for the development of the SBMS is 550-
700 700°C, for a maximum P of 1 GPa. If one then assumes that the enstatite–sapphirine pair was
701 stable in the source rock, the low Al-content of enstatite points to temperatures around 600-
702 650°C and pressures of a few kilobars (Fig. 4 in Gasparik, 1994). Furthermore, the instability of
703 the alternative assemblage cordierite–spinel implies a *minimum* P, decreasing at such
704 temperatures from ~0.3 GPa to ~0.1 GPa with decreasing H_2O activity (Podlesskii *et al.*, 2008,
705 his Fig. 7), which is definitely the case in the presence of metamorphic brines (e.g. Aranovich
706 & Newton, 1997).

707 The Lherz area is, together with the Boucheville basin, the place where the North
708 Pyrenean HT-LP Cretaceous metamorphism reached the highest temperatures (Golberg &
709 Leyreloup, 1990; Clerc *et al.*, 2015; Chelalou *et al.*, 2016). In the Aulus Basin, the highest peak
710 temperature has been so far estimated to a maximum of 625°C by RSCM in Liassic rocks
711 located 1.5 km to the south of the Lherz body, whereas peak temperatures around 550°C are
712 commonly obtained in Triassic (1 km to the south of the Lherz body) and Jurassic (300 m to
713 4.4 km from the Lherz body edges) metasediments (Clerc *et al.*, 2015). Hence, the SBMS
714 records metamorphic T conditions that equal or slightly exceed the highest values in the area.

715 In the context of extreme crustal thinning during the formation of the Aulus Basin
716 (Lagabrielle *et al.*, 2016), the maximum P conditions for the formation of the SBMS are
717 directly linked to the initial thickness of the pre-rift (Triassic to Aptian) + syn-rift (Albian to
718 Turonian) sedimentary pile above the exhumed mantle. Compilation of existing stratigraphic
719 data at the scale of the entire NPZ suggests a maximum thickness around 6-8 km for that
720 sedimentary pile (*e.g.* Debroas, 1978; Canérot & Delavaux, 1986; Canérot, 1991). Therefore,
721 the combined experimental and thermodynamic data allowing for sapphirine formation in the
722 0.1 - 0.2 GPa range, especially at relatively 'low' T near 600 - 650°C and under reduced H₂O
723 activity (Podlesskii *et al.*, 2008), are consistent with the geological constraints.

724 C. Timing of the events experienced by the SBMS

725 The U-Pb dating of rutile, which provide an apparent Cenomanian age (see section
726 IV.D.), must be confronted with mineralogical and textural features before being ascribed to
727 the formation of the SBMS. Three *a priori* scenarii may be envisioned. (1) The dated rutile
728 grains originate from a Variscan protolith which was brecciated and sedimented before the
729 Cenomanian. This sediment was re-heated during the Cretaceous HT-LP metamorphic
730 episode. (2) The protolith of samples BCOR 68a-b experienced a unique metamorphic episode
731 that occurred during the Cretaceous and it was subsequently brecciated and sedimented at a
732 shallow depth during the Upper Cretaceous. (3) Same history as (2) but brecciation and
733 sedimentation occurred later, most likely during the Paleogene Pyrenean shortening and even
734 more recently regarding sedimentation. We discard hypothesis (1) on the basis of three
735 arguments. As mentioned previously, Variscan rocks with such mineralogy and compositions
736 are unknown in the regional basement. Moreover, even though such rocks would be a very
737 discrete component of that basement, it is quite impossible to imagine that the sediments
738 contain only clasts issued from that component whilst common major minerals from the

739 Variscan crust, namely quartz and feldspars issued from granitoids and felsic metamorphic
740 rocks, are lacking (Tab. 2). Finally, hypothesis (1) is not consistent with the rock textures.
741 Closure temperature of the U-Pb system in rutile is strongly controlled by the grain size and
742 considered to be around 600°C for crystals with sizes ranging from 100 to 200 µm, although it
743 can be as low as *ca.* 400°C (Cherniak, 2000; Mezger *et al.*, 1989; see also Meinhold, 2010;
744 Blackburn *et al.*, 2011). Such a temperature range is however compatible with the Cretaceous
745 metamorphic peak temperatures known in the Lherz area (Clerc *et al.*, 2015), *i.e.* with
746 amphibolite facies. In such conditions, recrystallization of a sediment associating clasts of very
747 different size and compositions would induce characteristic textural features such as growth
748 of large clasts at the expense of minor similar ones at their contact, which is never observed.
749 Rather, all the observed textures argue for fracturing, disaggregation and dispersion of the
750 largest crystals (see section V.A.1). Accordingly, we consider that the *ca.* 100 Ma date does
751 not correspond to a resetting event. Hypothesis (3) is also difficult to reconcile with the fact
752 that none of the samples forming the SBMS display clasts deriving from the surrounding
753 Jurassic to Cretaceous formations of the Aulus Basin which fed however the volumetrically
754 very dominant Lherz breccias. On the opposite, hypothesis 2 fits U-Pb geochronological data
755 and the prevalence of ultramafic and Triassic clasts in the sapphirine-bearing breccias and
756 their systematic location in contact with ultramafic bodies. Accordingly, we conclude that
757 metamorphism and brecciation occurred during the Cretaceous rifting event. The timing of
758 sedimentation is however poorly constrained.

759

760 D. A possible model of emplacement of the sapphirine-bearing rocks

761 The sapphirine-bearing rocks are found only in a contact zone at the border of the
762 Lherz body and constitute the lowermost unit of the Lherz breccias. Therefore, according to

763 recent models of subcontinental mantle exhumation in the NPZ (*e.g.* Jammes *et al.*, 2009;
764 Lagabrielle *et al.*, 2016), they are good candidates to represent the basal portion of the
765 metamorphic sedimentary pile that came in tectonic contact with the exhumed peridotites
766 during the Cretaceous extensional event. The T estimates for the crystallization of the SBMS
767 material (550°C - 700°C, and more probably 600 - 650°C) as well as the U-Pb geochronological
768 data are consistent with a formation contemporaneous with the Pyrenean high T
769 metamorphic event, *i.e.* during the activity of the detachment fault which accommodated the
770 uplift of the peridotites beneath the opening Aulus Basin (Fig. 12).

771 In this study, we have reported numerous evidence for a dominant Keuper origin of
772 the material reworked in the sapphirine-bearing rocks. We also argued that the SBMS
773 protolith(s) derive from the metasomatic transformation of tectonized Keuper evaporitic
774 sediments under the influence of fluid circulations. Thus, we may speculate that the SBMS
775 protolith(s) originated along a major detachment fault at the final stages of the extreme
776 crustal thinning when the mantle rocks reached the base of the Mesozoic sedimentary pile,
777 under severe temperature conditions.

778 Our understanding of the Cretaceous mantle exhumation processes in the Pyrenees
779 lacks geological constraints and still remains incomplete. In this topic, our study provides the
780 following results: (i) the brecciated texture and the presence of unequivocal sedimentary
781 features in the sapphirine-bearing rocks show that the metasomatized Keuper material first
782 crossed the ductile-brittle transition and was then mechanically disaggregated before
783 experiencing some kind of winnowing in underwater conditions and (ii) we infer that these
784 rocks underwent minor spatial remobilization since their surface exposure, which is
785 consistent with the poor mixing observed between the different sources. Accordingly, the
786 most plausible scenario for the origin of the sapphirine-bearing rocks that integrates all our

787 observations is as follows: (i) the progressive exhumation of the extensional detachment and
788 its footwall toward shallow levels induced the transition from ductile to brittle deformation
789 responsible for the initial fracturing of the rocks and crystals; (ii) uplift was accompanied by
790 progressive unroofing of deep levels of the detachment fault on the floor of the basin; (iii)
791 exposure of the fault rocks allowed the reworking and primary sorting of the cataclastic
792 material by gravity-driven processes. Determining whether these latter reworking processes
793 occurred entirely during the exhumation event or somewhat later is beyond the scope of the
794 present paper and needs a discussion of the whole system of the Lherz breccias, including the
795 overwhelming carbonate-types.

796 In this scenario, the status of the sparitic calcite which forms the cement between the
797 fragments and fills cracks within monomineralic clasts in Type II samples is equivocal. It might
798 be a primary component (ophicalcitic cement, as exemplified by Denny *et al.*, 2016, or
799 dolomitic component of Keuper sediments themselves), metamorphosed and subsequently
800 redistributed, or it might have been introduced only during the brecciation stage like the
801 calcitic cement of the Lherz breccias. Deciphering between these two hypotheses requires
802 further investigation (*e.g.* RSCM, stable isotopes geochemistry).

803

804 VI. Conclusion

805 This detailed petrographic study of sapphirine-bearing rocks exposed in a contact zone
806 between the Lherz mantle peridotites and the Lherz breccias reveals that some samples are
807 composed of polymineralic clasts and isolated minerals that derive from well-recognized
808 protoliths, mostly ultramafic rocks and Triassic meta-ophites and "micaceous hornfels";
809 however, a large portion of the sapphirine-bearing clastic suite is composed of mono- and
810 polymineralic debris that derive from unknown protolith(s). We thus defined a "sapphirine-

811 bearing mineral suite" (SBMS) composed of monomineralic debris including: sapphirine +
812 enstatite + aluminous spinel + Mg-amphiboles + Ca-amphiboles + kornerupine + accessory
813 minerals (tourmaline, rutile, vermiculite and smectite).

814 The mineralogical study of the SBMS points to a peculiar Al-Mg-rich chemistry and
815 reveals the presence of F-, Cl-, Sr-rich evaporitic inclusions in minerals of the Al-Mg-rich suite.
816 This is consistent with a derivation of the SBMS from the metamorphic transformation of
817 Keuper evaporitic sediments under high T and low P conditions, typical of the Cretaceous
818 Pyrenean metamorphism. This contradicts the former interpretation of the Lherz sapphirine-
819 bearing suite as crustal basement felsic rocks modified at depth along the contact with the
820 ultramafic rocks of the Lherz body during their ascent towards shallower depths. Our
821 hypothesis is also supported by the location of the sapphirine-bearing rocks at the precise
822 contact zone between the exhumed Lherz body and the Lherz breccias.

823 According to recent models of subcontinental mantle exhumation in the NPZ
824 (Lagabrielle & Bodinier, 2008; Clerc *et al.*, 2015; Lagabrielle *et al.*, 2016), we propose that the
825 sapphirine-bearing rocks represent the first formation deposited over the peridotites exposed
826 on the floor of the Aulus Basin due to the activity of a detachment fault. The T estimates for
827 the crystallization of the SBMS material (550°C - 700°C, and more probably 600 - 650°C) and
828 U-Pb ages of *ca.* 100 Ma obtained on rutile are consistent with a formation contemporaneous
829 with the Pyrenean HT metamorphic event, which is during the activity of the fault that
830 accommodated the uplift of the peridotites beneath the opening Aulus Basin.

831 Field and microscopic observations imply that the sapphirine-bearing sandstones and
832 breccias formed in a context of active tectonics allowing for the brecciation of a variety of
833 lithological assemblages and their mechanical and sedimentary mixing. A scenario that
834 integrates all our observations is as follows: (i) initial fracturing of the rocks and crystals due

835 to progressive uplift of the extensional detachment toward shallow levels crossing the
836 transition from ductile to brittle deformation; (ii) progressive unroofing of deep levels of the
837 detachment fault on the floor of the basin; (iii) exposure of the fault rocks followed by
838 reworking and primary sorting of the cataclastic material by gravity-driven processes.

839

1084 **Figure 1:** 1) Geological sketch map of the Pyrenees showing the location of the Lherz body.

1085 NPFT, North-Pyrenean Frontal Thrust; NPF, North-Pyrenean Fault; SPF, South-Pyrenean Fault;

1086 SPFT, South Pyrenean Frontal Thrust (modified after Corre *et al.*, 2016). 2) Geological map of

1087 the Aulus Basin (modified after Lagabrielle *et al.*, 2016). Locations of the studied sites 1 and 2

1088 are indicated by red stars. Units of massive carbonates are separated by wide areas of

1089 polymictic sedimentary breccias. The ultramafic-bearing breccias are restricted to the central

1090 part of the Aulus Basin where the peridotite bodies are concentrated. Peak temperatures

1091 obtained by RSCM (Raman Spectroscopy of Carbonaceous Material) geothermometry on

1092 Mesozoic marble samples are from Clerc *et al.* (2015). **Site 1:** 42°48'30.52"N 1°22'52.85"E.

1093 **Site 2:** 42°48'26.78"N 1°23'7.97"E.

1094

1095 **Figure 2:** Field photographs from site 1. 1) Succession of clastic layers at site 1. Four layer

1096 types can be distinguished (see text for complete description). The dominant Layer A

1097 corresponds to light grey, coarse sandstones. Layer B corresponds to dark-brown layers of

1098 ultramafic breccias and microbreccias composed of dominant angular clasts of serpentinized

1099 lherzolite in an ultramafic sandy matrix. Layer C is represented by breccias and sandstones

1100 made of dominant ultramafic and minor cm-sized clasts of Triassic meta-ophite. Layer D is a

1101 coarse breccia composed of cm- to dm-sized angular clasts of ultramafic rock, white

1102 microbreccias, Triassic to Lower Jurassic meta-ophites and « micaceous hornfels ». 2) Sharp

1103 contact between Layer B ultramafic breccias (left) and light-grey Layer A sandstones (right). 3)

1104 Close up of gradded-bedding observed in Layer B microbreccias. 4) Detail view of Layer D

1105 breccia.

1106

1107 **Figure 3:** Field photographs from site 2. **1)** Photograph of the contact zone between the
1108 mantle peridotites and the Lherz breccias at site 2 and location of the sapphirine-bearing
1109 rocks sampling site (red star). White dotted lines underline the progressive transition existing
1110 between the Lherz body and the Lherz marble breccias. Around white dotted line n°1, a
1111 progressive transition from the sapphirine-bearing rocks to the pure marble breccias and
1112 microbreccias was observed. **2)** Detailed view of the sampling site 2 and location of close up
1113 photographs 3 and 4 shown below. **3)** Detailed view of the left side of exposure. It consists of
1114 a pale-green to light-grey microbreccia showing a rough bedding with layers of thin-grained
1115 sandstones dipping to the south-east (dashed lines). The microbreccia contains numerous cm-
1116 sized angular clasts of variable lithologies including “micaceous hornfels” and poorly
1117 serpentinized lherzolite (white outlines, determined on thin-sections). **4)** Detailed view of the
1118 right side of exposure. Sandstones include numerous cm-sized angular clasts of variable
1119 compositions (white outlines). One black clast of meta-ophite is observed macroscopically
1120 (bottom right side of photograph).

1121 **Table 1:** Main features of the different rock-types which constitute the sample collection.
1122 Simplified sketches are provided for each rock-type, taking into account their main features.
1123 Different colours indicate different mineral species. *Abbreviations from Whitney & Evans*
1124 (2010).

1125

1126 **Table 2:** Mineralogy of the sample collection. *Abbreviations from Whitney & Evans (2010).*

1127

1128 **Figure 4:** Thin-section micrographs showing the main features of Type I samples. **1)**
1129 « Micaceous hornfels » clast. Note the poikiloblastic texture of the central scapolite, with
1130 numerous inclusions (plane-polarized light; sample BCOR 71). **2)** « Micaceous hornfels » clast.
1131 Note the tourmaline and anorthite inclusions in the central scapolite (plane-polarized light;
1132 sample BCOR 71). *Abbreviations from Whitney & Evans (2010).*

1133

1134 **Figure 5:** Representative micrographs of Type II samples. **1)** Representative example of the
1135 sapphirine-bearing microbreccias (cross-polarized light; sample BCOR 68a). Note the
1136 dominant highly fractured monomineralic clasts and the calcitic cement. One fractured
1137 polymineralic clast (sapphirine + gedrite) appears in the upper central part of the picture
1138 (redrawn in the inset). **2)** Plurimillimetric monomineralic clast of gedrite fragmented with very
1139 few displacements between the debris (cross-polarized light; sample BCOR 68a). **3)** Sapphirine
1140 crystal showing corrosion gulls infilled with calcite, surrounded by kinked vermiculite crystals
1141 displaying open cleavages (cross-polarized light; sample BCOR 68b). **4)** A highly fractured
1142 subhedral anthophyllite crystal, with calcite infill (plane-polarized light; sample BCOR 72). **5)**
1143 and **6)** Polymimetic clasts showing the intergrowth relationships between sapphirine and
1144 gedrite (cross-polarized light; sample BCOR 68a). *Abbreviations from Whitney & Evans (2010).*

1145

1146 **Figure 6:** Representative micrographs of Type III samples. **1)** Polymineralic clast of sapphirine
1147 + gedrite showing textural equilibrium between the two phases (redrawn in the inset; cross-
1148 polarized light; sample BCOR 72). Areas appearing in brown in the sapphirine crystal
1149 correspond to voids generated when the thin section was prepared. **2)** Millimetric subhedral
1150 kornerupine crystal displaying parallel-oriented rutile inclusions (plane-polarized light; sample
1151 BCOR 72). **3)** Peridotite clast. Yellow dotted lines underline the limits of the polymineralic clast
1152 (plane-polarized light; sample Momo 1). **4)** Meta-ophite clast underlined by a red dotted line.
1153 Two ultramafic clasts are underlined by yellow dotted lines (plane-polarized light; sample
1154 Momo 1). **5)** Polymictic sandstone exclusively made of monomineralic clasts. A coarse
1155 bedding is underlined by planar minerals (black dotted arrows parallel to the bedding; plane-
1156 polarized light; sample LHZ 49). **6)** Polymineralic clast of scapolite (underlined by an orange
1157 dotted line) enclosed in a sandstone made of monomineralic clasts. Note the orientation of
1158 the vermiculite flakes, parallel to the borders of the scapolite clast (plane-polarized light;
1159 sample BCOR 73). *Abbreviations from Whitney & Evans (2010).*

1160

1161 **Figure 7:** Evidence of mineral fragmentation. **1)** Highly fractured plurimillimetric **crystal** of
1162 anthophyllite (left side) disaggregated into small angular pieces that fed the microbreccia
1163 (cross-polarized light; sample LHZ 7a). **4)** line drawing of 3) highlighting the fragmentation of
1164 anthophyllite. *Abbreviations from Whitney & Evans (2010).*

1165

1166 **Figure 8:** Evidence of layering at macro-scale. The mineral content of each layer is given in the
1167 inset. Dominant elements in each layer are shown in bold. **1)** Photograph of NR 94 sample.
1168 Layering is defined by alternating bluish (a) and yellow-orange layers (b), characterized by

1169 various grain sizes and by slightly different mineral compositions (see *Supplementary material*
1170 *SM2* for a complete description). **2)** Thin section photograph of sample Momo 1. A layering is
1171 underlined by red dotted lines.

1172

1173 **Figure 9:** Layering defined by overconcentration of minerals in BCOR 72 sample. **1)** Phase map
1174 (EDS analysis, elemental mapping). **2)** Surface percentage of each mineral species. *
1175 Undetermined, possibly weathered phases. ** Not observed in thin section.

1176

1177 **Table 3:** Representative analyses of the main phases of the SBMS. When several analyses are
1178 available for a mineral species, the average composition and the corresponding structural
1179 formula are given. For vermiculite and smectite, the structural formulae were not determined
1180 due to the great diversity of the microprobe analyses in our sample collection. *Average values*
1181 *are calculated on the basis of a) twelve analyses from four samples; b) twenty-nine analyses*
1182 *from two samples; c) seven analyses from three samples; d) five analyses from two samples; e)*
1183 *nine analyses from four samples; f) nineteen analyses from three samples; g) single analysis;*
1184 *h) three analyses from one sample; i) single analysis; j) five analyses from two samples; k)*
1185 *forty-six analyses from six samples; l) six analyses from two samples.*

1186

1187 **Figure 10:** Representative micrographs of the solid inclusions observed in minerals of the
1188 SBMS. **1)** Chlorapatite inclusion (outlined in blue) in a sapphirine crystal (reflected light;
1189 sample BCOR 68b). **2)** Anhydrite inclusion in a kornerupine crystal (Back-scattered electron
1190 image; sample BCOR 72). **3)** Coalescent anhydrite and chlorapatite inclusions in an Al-bearing
1191 enstatite crystal (cross-polarized light; sample NR 94). **4)** Clinochlore inclusions in aluminous

1192 enstatite (plane-polarized light; sample NR 94, modified from F. Foucard, unpublished master
1193 thesis, Toulouse, 1997). *Abbreviations from Whitney & Evans (2010).*

1194

1195

1196 **Table 4:** Electron-microprobe analyses of solid inclusions of evaporitic affinity in enstatite
1197 crystals from sample NR 94. *Average values of n analyses, with n= 6 for a), n= 3 for b), n= 5 for*
1198 *c).*

1199

1200 **Table 5:** LA-ICP-MS U-Pb isotope and age data for analyzed rutile grains in samples BCOR 72a-
1201 b. All errors are reported at 2σ . $f_{206\%} = (207\text{Pb}/206\text{Pb}_{\text{m}} - 207\text{Pb}/206\text{Pb}^*)/(207\text{Pb}/206\text{Pb}_{\text{c}} -$
1202 $207\text{Pb}/206\text{Pb}^*) \times 100$ with $207\text{Pb}/206\text{Pb}^*$ and $207\text{Pb}/206\text{Pb}_{\text{c}}$ calculated at 100 Ma.

1203

1204 **Figure 11:** Tera-Wasserburg concordia diagram for the U-Pb dating of rutile grains from
1205 samples BCOR68a-b. Error ellipses are plotted at 2σ . The lower intercept date of 98.6 ± 1.2
1206 Ma is also reported with an error at 2σ .

1207

1208 **Table 6:** Bulk-rock analyses by Monchoux (1972a). 1, 2, 3: sapphirine-bearing rocks devoid of
1209 calcite, found at an increasing distance from the Lherz body. 4, 5: sapphirine-bearing rocks
1210 with calcite. *L.o.i.: Loss on ignition.*

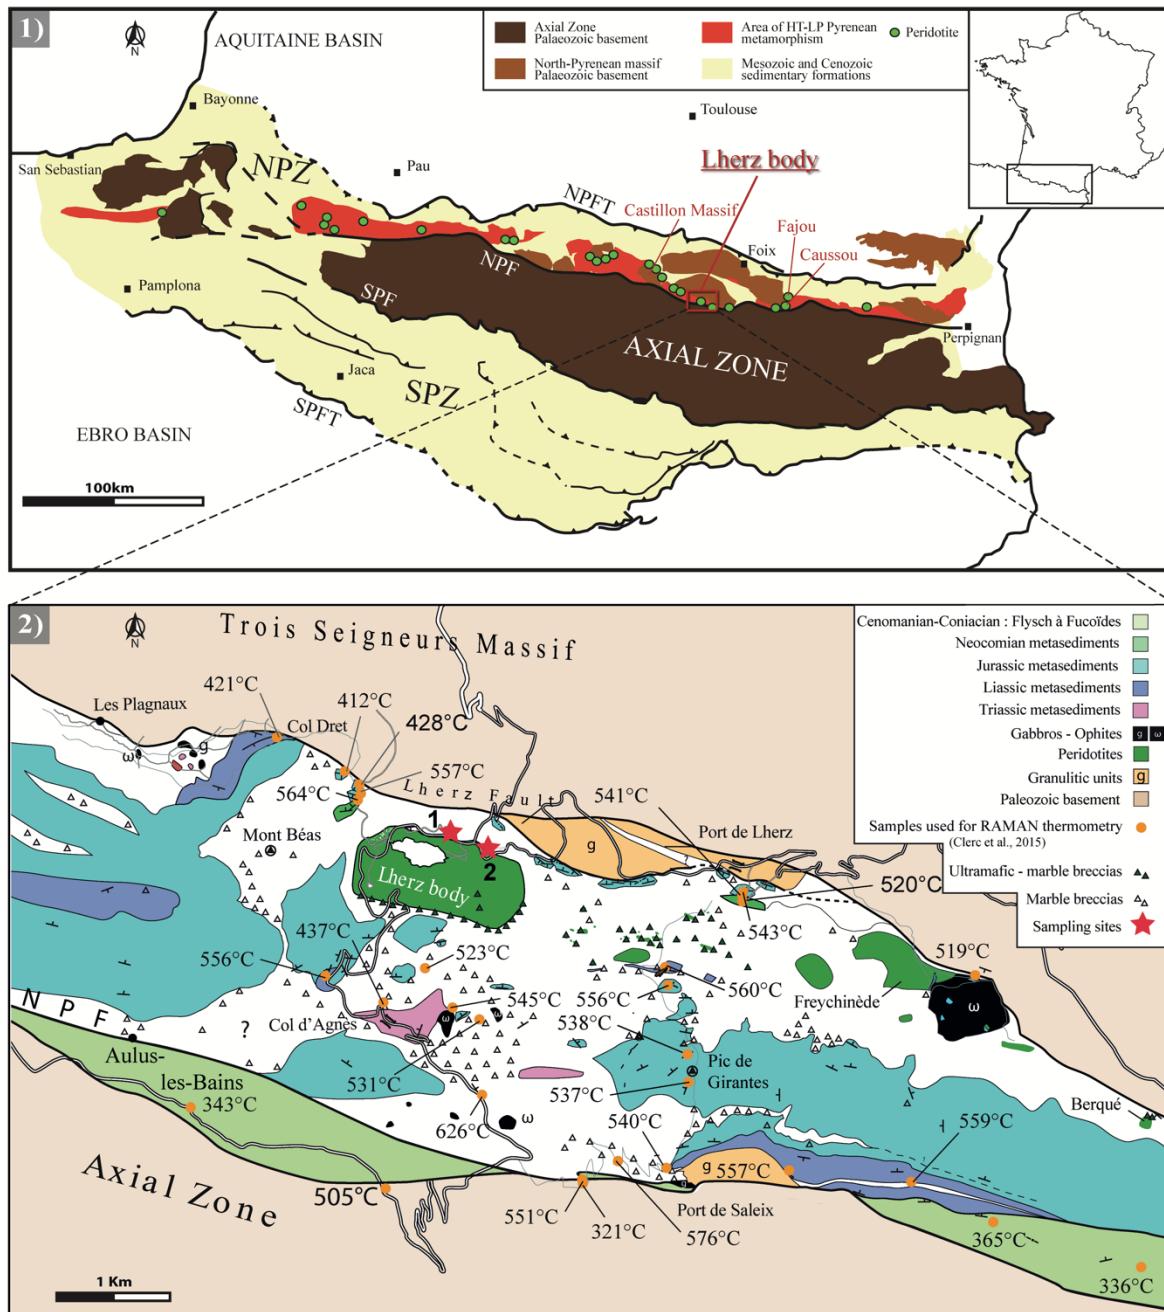

1211

1212 **Figure 12:** Position of the main protolith of the SBMS suggested from this study in the
1213 Pyrenean rift (red star). The geometry of the rift is redrawn after Duretz *et al.* (2019). The P-T
1214 conditions of metamorphism of the Upper Jurassic to Lower Triassic protolith on contact with

1215 the asthenospheric mantle deduced from this study are given with their uncertainties in the

1216 inset.

1217

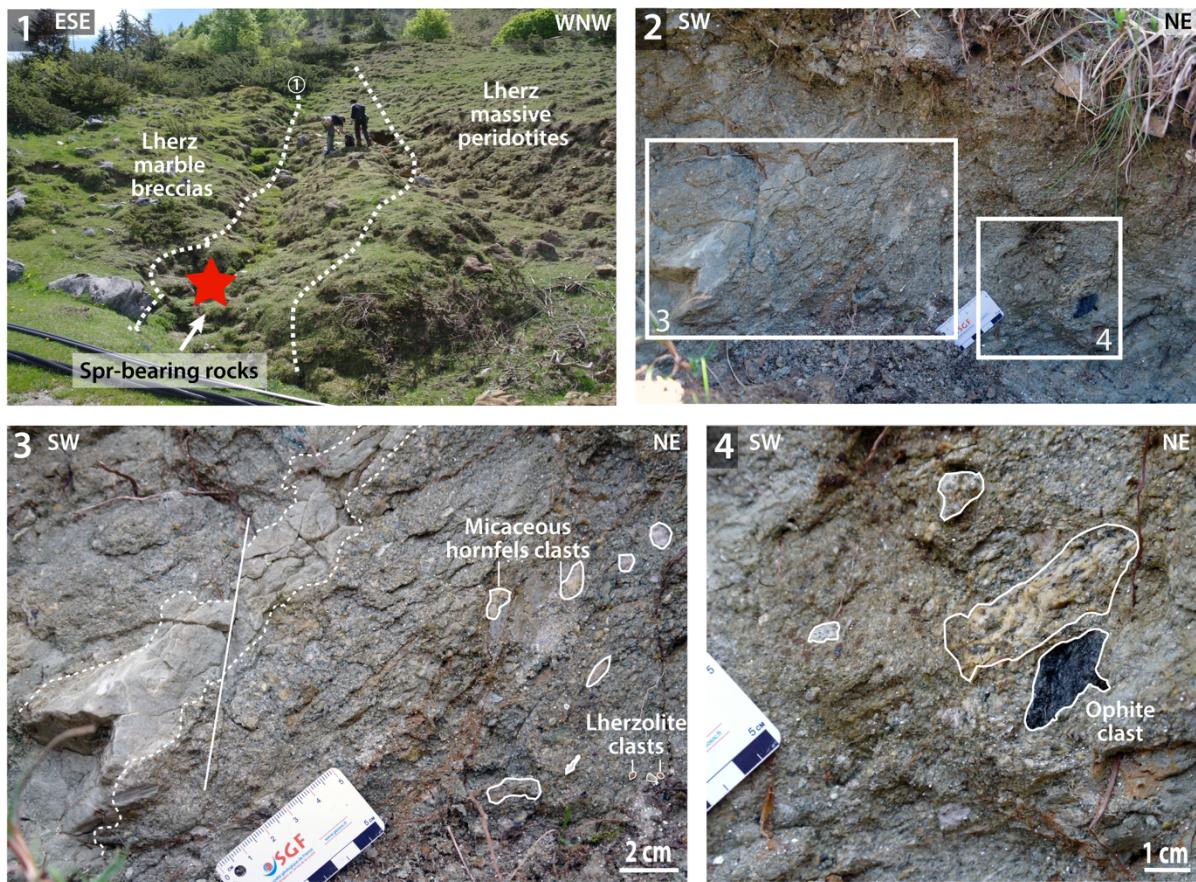

1220 **Figure 1 : 1)** Schéma structural simplifié des Pyrénées montrant la localisation du corps de Lherz.
1221 NPFT, Chevauchement Frontal Nord-Pyrénénien ; NPF, Faille Nord Pyrénénienne ; SPFT, Chevauchement
1222 Frontal Sud-Pyrénénien (modifié d'après Corre *et al.*, 2016). **2)** Carte géologique du Bassin d'Aulus
1223 (modifiée d'après Lagabrielle *et al.*, 2016). Les étoiles rouges indiquent la localisation des sites 1 et 2
1224 étudiés dans cet article. Les unités de carbonates massifs sont séparées les unes des autres par des
1225 brèches sédimentaires polygéniques. Les brèches à éléments ultramafiques sont observées au centre
1226 du Bassin d'Aulus, à proximité des corps de péridotite. Les températures obtenues par
1227 le géothermomètre RSCM (spectroscopie Raman de la matière carbonée) sur des échantillons de
1228 marbres mésozoïques sont tirées de Clerc *et al.* (2015).

1229 Site 1 : 42°48'30.52"N 1°22'52.85"E. Site 2 : 42°48'26.78"N 1°23'7.97"E.

1230

1231 **Figure 2 :** Photographies réalisées sur le site 1. **1)** Succession des niveaux clastiques du site 1. Quatre
 1232 types de niveau peuvent être distingués (se référer au texte pour une description complète). Le Lit A,
 1233 dominant, correspond à un sable gris clair grossier. Le Lit B est constitué de niveaux marrons sombres
 1234 de brèches et microbrèches ultramafiques, à clastes anguleux de lherzolite serpentinitisée majoritaires
 1235 dans une matrice ultramafique sableuse. Le Lit C correspond à des brèches et grès composés en
 1236 majorité de clastes ultramafiques, et de plus rares clastes centimétriques de méta-ophites triasiques.
 1237 Le Lit D est une brèche composée de clastes anguleux, de taille centimétrique à décimétrique, de
 1238 roches ultramafiques, de microbrèches blanches, de méta-ophites et de « cornéennes micacées »
 1239 triasiques à jurassiques inférieures. **2)** Contact franc entre les brèches ultramafiques du Lit B (à
 1240 gauche) et les grès gris clairs du Lit A (à droite). **3)** Vue détaillée du granoclassement observé dans les
 1241 microbrèches du Lit B. **4)** Vue détaillée de la brèche du Lit D.

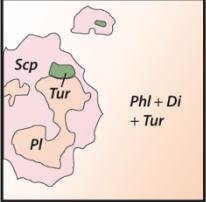

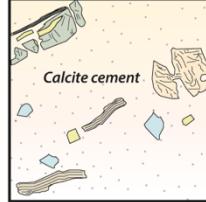

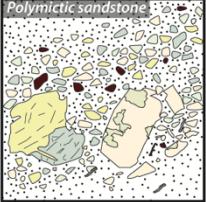

1242

1243 **Figure 3** : Photographies du site 2. **1)** Photographie de la zone de contact entre les périclites
 1244 mantelliques et les brèches de Lherz au niveau du site 2. La localisation du site d'échantillonnage des
 1245 roches à saphirine est représentée par l'étoile rouge. Les lignes blanches pointillées soulignent la
 1246 transition progressive qui existe entre le corps de Lherz et les brèches de Lherz à clastes de marbre.
 1247 A proximité de la ligne blanche pointillée n°1, nous avons observé une transition progressive entre
 1248 les roches à saphirine et les brèches et microbrèches formées uniquement de clastes de marbre. **2)**
 1249 Vue détaillée du site 2. La localisation des photographies 3 et 4 est représentée par les rectangles
 1250 blancs. **3)** Vue détaillée d'une portion de l'affleurement. Cette portion correspond à une microbrèche
 1251 de couleur vert pâle à grise claire et montre un litage formé de couches de grès fins à pendage vers le
 1252 sud-est (lignes pointillées). La microbrèche contient en outre des clastes anguleux centimétriques de
 1253 lithologies diverses incluant des « cornéennes micacées » et des lherzolites faiblement serpentinisées
 1254 (entourées en blanc, reconnues en lame mince). **4)** Vue détaillée de la seconde portion de
 1255 l'affleurement. Les grès contiennent de nombreux clastes anguleux centimétriques de compositions
 1256 variables (entourés en blanc). Un claste noir métaphytique est observable macroscopiquement
 1257 (partie inférieure droite de l'image).

1258 **Table 1 :** Caractéristiques principales des différents types de roches de la collection d'échantillons
 1259 étudiés dans cet article. Les schémas simplifiés se trouvant dans la dernière ligne du tableau mettent
 1260 en avant les caractéristiques principales des différents types de roches. *Les abréviations utilisées sont*
 1261 *tirées de Whitney & Evans (2010).*
 1262

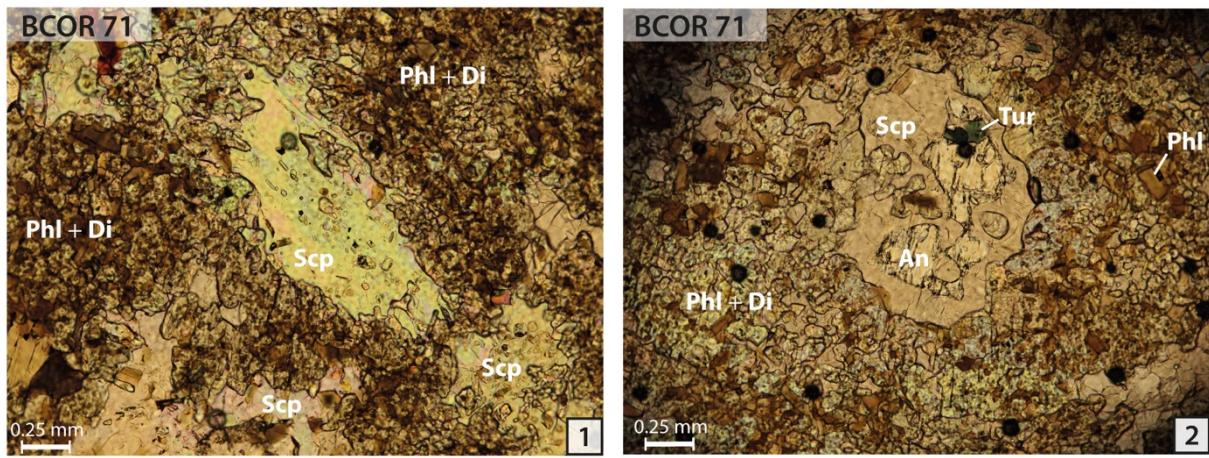

Table 1 : Caractéristiques principales des différents types de roches de la collection d'échantillons étudiés dans cet article.

Figure 4 : Microographies de lames minces montrant les principales caractéristiques des échantillons de Type I. 1) Claste de « cornéenne micacée ». Noter la texture poeciloblastique de la scapolite centrale, qui contient de nombreuses inclusions (lumière polarisée non-analysée ; échantillon BCOR 71). 2) Autre claste de « cornéenne micacée ». Noter les inclusions de tourmaline et d'anorthite dans la scapolite centrale (lumière polarisée non-analysée ; échantillon BCOR 71). *Les abréviations utilisées sont tirées de Whitney & Evans (2010).*

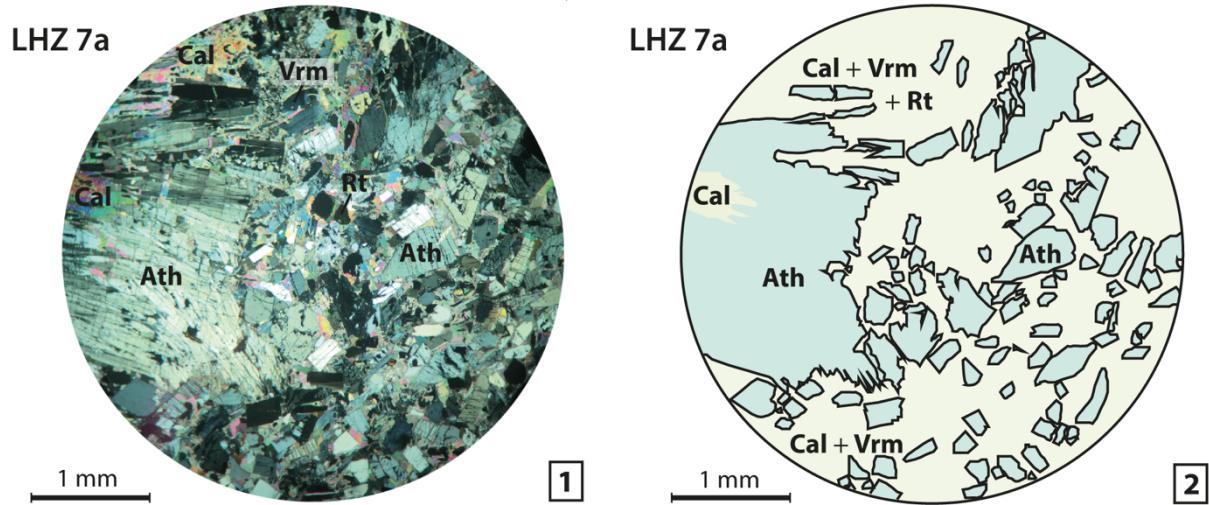

1276
1277

1278 **Figure 5 :** Micrographies de lames minces montrant les principales caractéristiques des échantillons de
1279 Type II. **1)** Exemple représentatif des microbrèches à saphirine (lumière polarisée analysée ;
1280 échantillon BCOR 68a). Noter la prédominance des clastes monominéraux très fracturés et la présence
1281 d'un ciment calcique. Un claste polyminéral (saphirine + gédrite) fracturé est présent dans la partie
1282 supérieure centrale de l'image (redessiné dans l'encart). **2)** Clastes monominéraux de gédrite,
1283 plurimillimétriques et fragmentés dont les débris sont peu éloignés les uns des autres (lumière
1284 polarisée analysée ; échantillon BCOR 68a). **3)** Cristal de saphirine à golfes de corrosion remplis de
1285 calcite, entourés de vermiculites kinkées à clivages ouverts (lumière polarisée analysée ; échantillon
1286 BCOR 68b). **4)** Cristal d'anthophyllite subautomorphe très fracturé et rempli de calcite. **5)** et **6)** Clastes
1287 polyminéraux montrant des intercroissances de saphirine et gédrite (lumière polarisée analysée ;
1288 échantillon BCOR 68a). Les abréviations utilisées sont tirées de Whitney & Evans (2010).

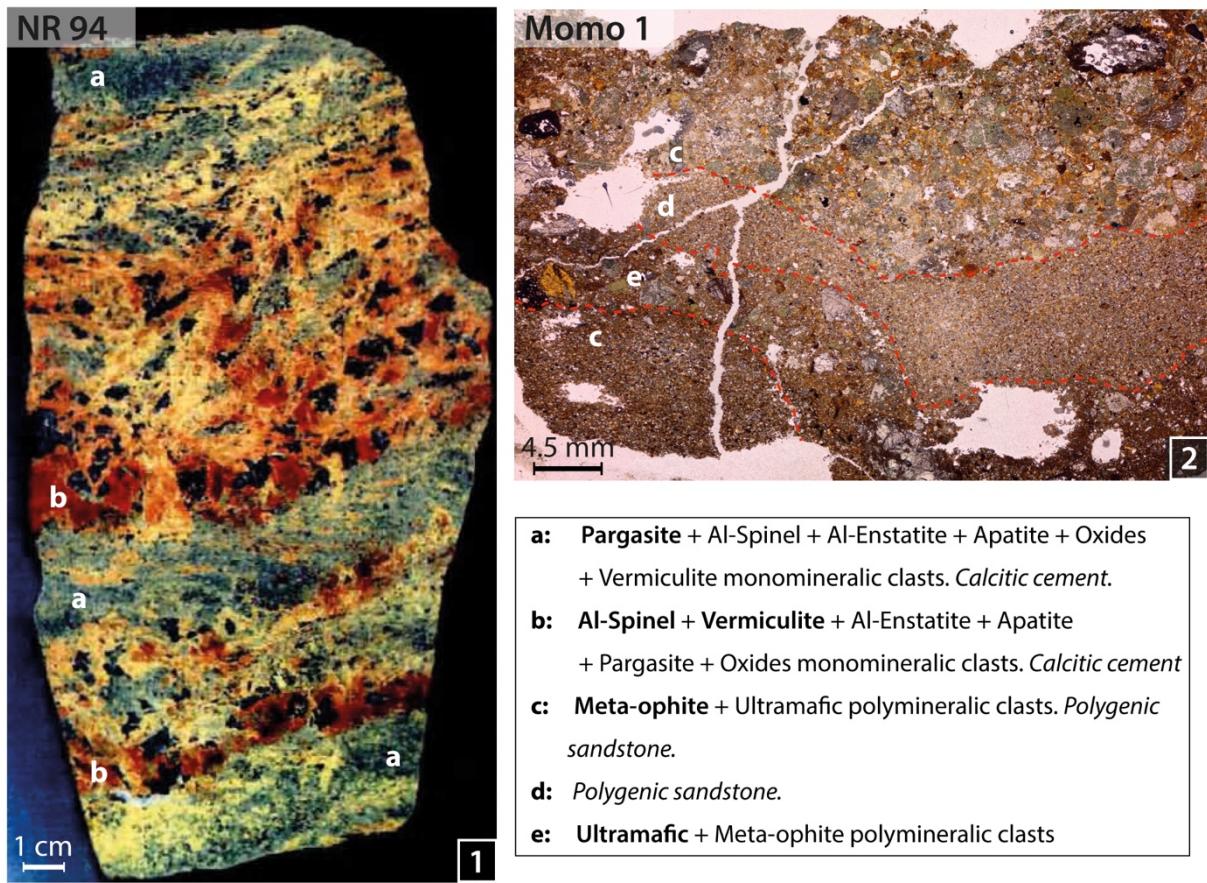

1289
1290 **Figure 6 :** Micrographies de lames minces montrant les principales caractéristiques des échantillons de
1291 Type III. 1) Claste polyminéral à saphirine + gédrite en équilibre textural (redessiné dans l'encart ;
1292 lumière polarisée analysée ; échantillon BCOR 72). Les portions qui apparaissent en marron au sein de
1293 la saphirine correspondent à des vides générés au moment de la préparation de la lame mince. 2)
1294 Cristal de kornérupine millimétrique subautomorphe à inclusions de rutile parallèles les unes aux
1295 autres (lumière polarisée non-analysée ; échantillon BCOR 72). 3) Claste périclitique. Les lignes
1296 pointillées jaunes soulignent les contours du claste ultramafique (lumière polarisée non-analysée ;
1297 échantillon Momo 1). 4) Claste métaphytique (souligné par la ligne rouge pointillée). Deux clastes
1298 ultramafiques sont soulignés par les lignes jaunes pointillées (lumière polarisée non-analysée ;
1299 échantillon Momo 1). 5) Grès polygénique constitué de clastes monominéraux. Un litage grossier est
1300 souligné par les minéraux planaires (l'orientation des flèches est parallèle au litage ; échantillon LHZ
1301 49). 6) Claste polyminéral de scapolite (souligné par la ligne orange pointillée) dans un grès constitué
1302 de clastes monominéraux. Notez l'orientation des vermiculites, parallèles aux bordures du claste de
1303 scapolite (lumière polarisée non-analysée ; échantillon BCOR 73). *Les abréviations utilisées sont tirées*
1304 *de Whitney & Evans (2010).*

Figure 8 : Evidences de litage à l'échelle macroscopique. Les compositions des lits sont données dans l'encart. Les éléments dominants dans chaque couche sont figurés en gras. 1) Photographie de l'échantillon NR 94. Un litage est défini par l'alternance de couches bleues (a) et oranges à jaunes (b) qui sont caractérisées par des tailles de grains variables et par des compositions légèrement différentes (se référer aux ressources supplémentaires SM2 pour une description complète de l'échantillon). 2) Photographie de lame mince de l'échantillon Momo 1. Le litage est souligné par les lignes rouges pointillées.

1324
1325 **Figure 9 :** Litage défini par l'accumulation de minéraux dans l'échantillon BCOR 72. **1)** Cartographie
1326 élémentaire de l'échantillon BCOR 72 (Carte des phases ; analyse dispersive en énergie).
1327 **2)** Pourcentage de la surface occupée par chaque espèce minérale dans l'échantillon.
1328 * Espèces non identifiées, potentiellement altérées. ** Non observé sur la lame mince.

Table 3 : Analyses représentatives des principales espèces de l'assemblage minéralogique à saphirine. Lorsque plusieurs analyses sont disponibles, une composition moyenne et la formule structurale correspondante sont calculées. Les formules structurales n'ont pas été calculées pour la vermiculite et la saponite du fait de l'importante diversité des analyses microsonde obtenues dans notre collection d'échantillons.
