Quantifying nutrient attenuation at watershed scales requires long-term water chemistry data, water discharge, and detailed nutrient input chronicles. Consequently, nutrient attenuation estimates are largely limited to long-term research areas or modeling studies, constraining understanding of the ecological characteristics controlling nutrient attenuation and complicating efforts to protect or restore water quality in developed and developing regions. Here, we combined long-term data and a broad suite of biogeochemical parameters from 49 watersheds in northwestern France to test how well instantaneous measurements can predict nitrogen (N) and phosphorus (P) attenuation at watershed scales. We evaluated 13 biogeochemical and 12 hydrological proxies of hydrological flowpaths, residence time, and biogeochemical transformation. Across the 49 watersheds, nutrient attenuation ranged from 88 to −2% for N and 99–96% for P. The strongest biogeochemical proxies of N attenuation were NO₃[−] isotopes, rare earth elements (REEs), radon, and turbidity, together explaining 75% of observed variation. For P attenuation, REEs, NO₃[−] isotopes, molecular weight of dissolved organic matter, and radon were the strongest proxies, but only explained 27% of observed variation. However, a single hydrological parameter—annual runoff—explained 91% of N attenuation and the relative abundance of schist bedrock explained 56% of P attenuation. We discuss how runoff both controls and reflects watershed hydrology, biogeochemistry, and nutrient attenuation. For example, runoff was correlated with long-term decreases in nutrient concentration, demonstrating how leakier watersheds recover more quickly from nutrient saturation. Given the immense fertilization capacity of modern society, we propose that eutrophication can only be solved by reducing nutrient inputs, though hydrochemical proxies can provide valuable information on where to carry out essential food production activities.

Keywords: nitrogen, phosphorus, attenuation, biogeochemical proxy, nutrient legacy

INTRODUCTION

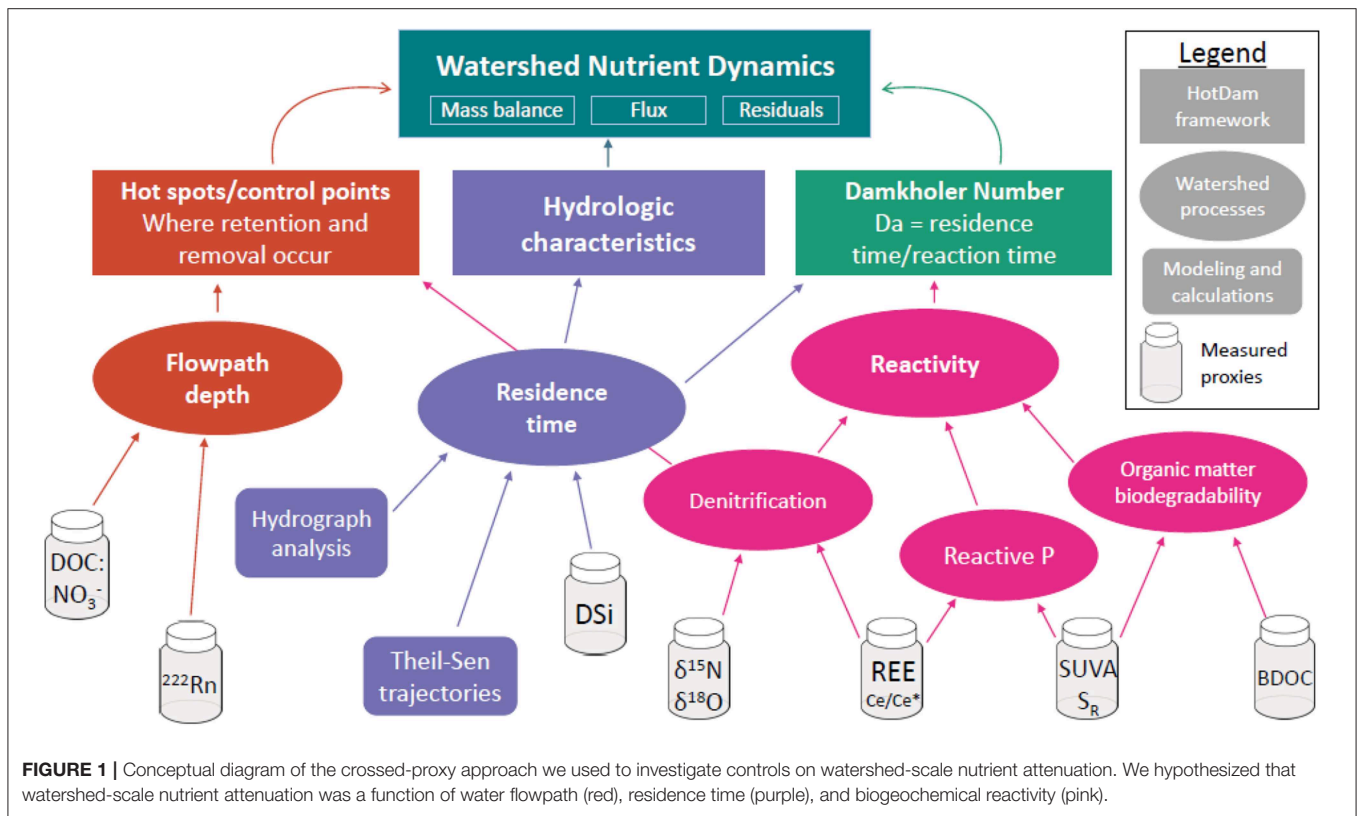

115 Since the Industrial Revolution, humans have more than doubled
116 reactive nitrogen (N) inputs (Gruber and Galloway, 2008) and
117 quadrupled phosphorus (P) inputs (Elser and Bennett, 2011)
118 into the Earth's ecosystems (Seitzinger et al., 2010; Foley et al.,
119 Q6 2011; Abbott et al., 2018a). Consequently, 80% of freshwater and
120 coastal ecosystems now experience eutrophication induced by
121 anthropogenic inputs of N and P (Howarth et al., 2000; Galloway
122 Q8 et al., 2003; Poisvert et al., 2017; Le Moal et al., 2019). Though
123 recognized as a planetary priority (Foley et al., 2011; Steffen
124 Q23 et al., 2015; Le Moal et al., 2019), efforts to reduce eutrophication
125 have had mixed results, partly because of two challenges that
126 emerge at watershed scales (i.e., 1–10,000 km²). First, is the
127 difficulty to quantify the overall residence time of nutrients in
128 complex watersheds, which ranges from minutes to millennia
129 as nutrients may be recycled or stored in plant biomass, soil,
130 and groundwater (Jarvie et al., 2013; Sebilo et al., 2013; Marçais
131 et al., 2018; Carey et al., 2019; Kolbe et al., 2019). Second, the
132 capacity of ecosystems to remove or permanently retain nutrients
133 via vertical processes such as denitrification or diagenesis is
134 highly variable, and the socioecological drivers (e.g., watershed
135 characteristics and agricultural practices) of nutrient removal are
136 poorly understood (Pinay et al., 2015; Abbott et al., 2016; Dupas
137 et al., 2018; Goyette et al., 2018; Jarvie et al., 2019).

140 There are three general fates for nutrients moving through
141 the soils, riparian zones, surface waters, and aquifers of a
142 watershed: (1) Retention (i.e., a long or short-term delay) by
143 biological and physical processes, including nutrient uptake,
144 sorption, or hydrological residence time (Covino et al., 2010;
145 Sebilo et al., 2013; Van Meter et al., 2016; Dupas et al., 2017;
146 Ehrhardt et al., 2019), (2) Vertical removal to the atmosphere
147 or lithosphere, including denitrification, aeolian transport, or
148 mineral precipitation with various metals (Groffman et al., 2006;
149 Seitzinger et al., 2006; Pinay et al., 2018; Randall et al., 2019),
150 and (3) Longitudinal export from the watershed via surface or
151 subsurface flow (Burt and Pinay, 2005; Seitzinger et al., 2010;
152 Abbott et al., 2018a). The reactivity and mobility of organic
153 and inorganic nutrients depend on and influence biogeochemical
154 conditions (Abbott et al., 2016; Bernhardt et al., 2017), meaning
155 that the fate of carbon, N, and P can vary substantially through
156 time (e.g., storm events or seasons) and in space (e.g., different
157 watersheds or biomes) (Dupas et al., 2016; Moatar et al., 2017;
158 Musolff et al., 2017; Minaudo et al., 2019). Consequently,
159 watersheds with similar nutrient inputs often have completely
160 different nutrient export regimes, particularly for headwater
161 watersheds that make up most of the terrestrial-aquatic interface
162 (Bishop et al., 2008; Abbott et al., 2018b; Helton et al., 2018;
163 Wollheim et al., 2018). This variability in nutrient attenuation
164 capacity is likely associated with differences in surface and
165 subsurface characteristics, including differences in water storage
166 capacity and residence times, abundance and activity of biotic
167 nutrient sinks (e.g., plant or microbial assimilation, dissimilatory
168 microbial metabolism) and abiotic factors (e.g., high sorption
169 capacity in soils, mineral precipitation, presence of chemical
170 reducers in bedrock) (Hansen et al., 2002; Aquilina et al., 2012,
171 2018; Thomas and Abbott, 2018; Kolbe et al., 2019). All these

factors are influenced by changes in hydrological connectivity, 172
uneven distribution of reactants and organisms due to the co- 173
evolution of surface and subsurface characteristics, and the 174
stochastic nature of human and natural disturbance (Hansen 175
et al., 2000; Thomas et al., 2015; Covino, 2017; Moatar et al., 176
2017). 177

178 Despite advances in understanding nutrient dynamics, it 179
remains difficult to quantify nutrient retention and removal 180
on timescales matching hydrological and nutrient residence 181
times (Vitousek, 2004; Pinay et al., 2015; Feng et al., 2018; 182
Ehrhardt et al., 2019). Additionally, many nutrient attenuation 183
studies focus on single-nutrient dynamics, despite the fact 184
that eutrophication is caused by interactions among multiple 185
nutrients and factors (Carpenter et al., 1998; Elser et al., 186
2007; Paerl et al., 2016; Hobbie et al., 2017; Le Moal et al., 187
2019). Consequently, there is no straightforward way to predict 188
a watershed's sensitivity to high nutrient inputs, seriously 189
limiting our ability to prevent eutrophication or improve 190
water quality where it has already been degraded. Quantifying 191
nutrient attenuation at the watershed scale involves lengthy 192
data acquisition and costly infrastructure (Burt, 1994; Howden 193
et al., 2010; Burt et al., 2011), which are not always available 194
in developing nations where agriculture and urbanization are 195
intensifying fastest (Seitzinger et al., 2010; FAO ed., 2017; Dupas 196
et al., 2019b).

197 In this context of variability, two conceptual approaches 198
for predicting nutrient attenuation are the hot spots/control 199
points concept, which predicts where and when biogeochemical 200
reactions are more likely to occur (McClain et al., 2003; Bernhardt 201
et al., 2017) and the Damköhler number, which uses the ratio 202
of residence time to reaction time to predict how much of a 203
solute can be transformed or retained (Ocampo et al., 2006; 204
Zarnetske et al., 2011; Oldham et al., 2013). Pinay et al. (2015) 205
and Abbott et al. (2016) proposed to combine these concepts 206
in the HotDam framework by combining multiple proxies 207
of biogeochemical transformation, hydrological flowpaths, and 208
hydrological residence time. Combining or crossing multiple 209
proxies such as solute and isotopic concentrations, hydrograph 210
properties, and organic matter can illustrate terrestrial and 211
aquatic conditions across nutrient flowpaths (Pinay et al., 212
2015; Abbott et al., 2016; Shogren et al., 2019), potentially 213
paving the way for a more systematic understanding of what 214
controls nutrient attenuation in watersheds. Here, we apply 215
the HotDam framework to identify controls on attenuation 216
of N and P in 49 small to medium watersheds in Brittany, 217
France using a crossed-proxy approach. Our overarching goals 218
were to understand the drivers of nutrient attenuation in 219
agricultural watersheds and test how well nutrient attenuation 220
could be predicted with easily measurable proxies. These proxies 221
included nutrient stoichiometry, organic matter biodegradability, 222
dissolved gases, rare earth elements (REEs), nitrate isotopes, 223
and hydrograph parameters (Figure 1). We hypothesized that 224
nutrient attenuation would be controlled by the hydrological 225
properties of the watersheds (e.g., water residence time and 226
dominant flowpaths), surface and subsurface characteristics 227
(e.g., land use, topography, geology), and biogeochemical 228
conditions (e.g., stoichiometry and spatiotemporal distribution

of electron donors and acceptors; see **Table 1**). We tested these hypotheses by calculating mass balances of N and P for each watershed using 10 years of local, regional, or national agency data, and then sampling the watersheds three times across flow conditions and seasons to analyze the broad suite of proxies.

MATERIALS AND METHODS

Site Description and Experimental Design

The Brittany region of northwestern France has a rich repository of environmental data generated by academic and governmental research. For example, 27 of the 49 watersheds in this study had a nearby surface water monitoring station, which provided the concentration and discharge data necessary to calculate annual nutrient fluxes and long-term trends (Fovet et al., 2015; Thomas et al., 2019) and estimates of nutrient input were available for all watersheds (Poisvert et al., 2017). More generally, these intensively-managed, agricultural landscapes experience high but decreasing nutrient inputs, providing insight into how watershed-level nutrient fluxes respond to changes in nutrient loading (Galloway et al., 2008; Sutton et al., 2013; Poisvert et al., 2017). The region is a part of the Armorican massif which is composed of metamorphic and igneous rock, primarily granite, schist, and micaschist (Aquilina et al., 2012; Goderniaux et al., 2013; Kolbe et al., 2016). The climate is temperate oceanic, with a mean annual temperature of 11.2°C and mean annual rainfall ranging from 1,400 mm in the west to 600 mm in the

east, relatively well-distributed throughout the year (Gascuel-Oudoux et al., 2010; Thomas et al., 2015, 2019). The area has an average stream density of about 1 km km⁻², relatively shallow groundwater, and hydromorphic riparian soils that cover about 20% of the land surface (Mourier et al., 2008; Dupas et al., 2013; Marçais et al., 2018). Land use is dominated by row crops, indoor pig and poultry husbandry, and pastureland for cows (a mean of 80% agricultural cover across the study watersheds; **Table S1**), making Brittany one of the highest density regions in France and Europe for animal breeding (Gascuel-Oudoux et al., 2010; Poisvert et al., 2017; Kim et al., 2019). N and P concentrations in many Brittany watersheds are decreasing, attributable primarily to reduction of point sources such as wastewater and feedlot effluent (Moatar et al., 2017; Abbott et al., 2018b; Dupas et al., 2018).

We analyzed stream water chemistry in 49 agricultural watersheds ranging from 2.38 to 2,080 km² (**Figure 2**). Most of the watersheds were small to medium sized (mean area = 232 km², median area = 18.2 km²), which was a consequence of Brittany's geography as a peninsula and our design to capture variability in headwater watersheds that make up the majority of the land-water interface ((Burt and Pinay, 2005; Bishop et al., 2008; Heathwaite, 2010)). Sampling points were typically near the coast, but above the zone of tidal influence (**Figure 2**). To capture variable flow conditions and seasonal differences, we collected samples during 3 field campaigns in November 2015 (lowest flow), March 2016 (highest flow), and June 2018 (moderate flow; **Figure S1**). During each field campaign, we

TABLE 1 | List of proxies in our analysis and predictions of how they might affect nutrient attenuation.

Proxy	N attenuation	P attenuation	Flowpath	Residence time	Biogeochemical transformation	Explanation
DSi	+++	+++	x	x		Indicator of watershed residence time (Marçais et al., 2018)
$\delta^{15}\text{N}$ and $\delta^{18}\text{O}$	+++	---	x		x	More enriched NO_3^- isotopes indicate denitrification and requisite conditions (i.e., NO_3^- , anoxia, electron donor, denitrifying bacteria; Lehmann et al., 2003)
REE and Ce anomaly	+++	---	x		x	Ce anomaly is an indirect tracer of redox conditions and exposure to DOM (Gruau et al., 2004); a larger Ce anomaly correlates with anoxic conditions
Radon	+++	+++		x		High ^{222}Rn indicates deeper flowpaths (Bertin and Bourg, 1994)
SUVA ₂₅₄	---	+++	x		x	SUVA ₂₅₄ is an estimate for aromaticity of organic molecules (Weishaar et al., 2003); higher SUVA ₂₅₄ may correlate with lower bioavailability
S _R	+++	---	x		x	S _R is inversely related to molecular weight of CDOM (Helms et al., 2008); higher S _R correlates with lower molecular weight and may indicate more bioavailable compounds (Ewing et al., 2015)
BDOC	+++	---	x		x	BDOC measures biodegradability of DOM (McDowell et al., 2006); higher BDOC could stimulate denitrification but also nutrient mineralization
DOC:NO ₃ ⁻	+++	---	x		x	Stoichiometric ratios of C and N can indicate whether C or N attenuation is more likely (Sternner and Elser, 2002), and also indicate hydrologic flowpath because deep flowpaths have lower C:N ratios
pH	+++	---			x	As pH increases, organic colloids become more electronegative and release adsorbed phosphate particles (Gu et al., 2019), and C and N are more available (Glass and Silverstein, 1998)
Turbidity	---	---	x		x	Highly turbid systems have large amounts of suspended solids that can export nutrients downstream and limit in-network attenuation
Conductivity	---	---	x		x	High conductivity can indicate groundwater inputs or agricultural and urban runoff

Proxies were chosen because they are indicative of hydrologic flowpath, residence time, and/or biogeochemical transformations.

Predicted relationships between proxies and nutrient attenuation assumes increasing concentrations (e.g., higher concentrations of DSi are hypothesized to increase attenuation of N and P).

sampled all 49 sites within 1 week to capture watershed signals in comparable hydrological conditions. Seventeen of the watersheds were independent drainage basins and 32 were nested within the Couesnon and Rance watersheds (23 and 9 nested subwatersheds, respectively), allowing us to assess nutrient attenuation controls across a greater range of watershed sizes (Figure 2) and take advantage of previous research on those sites (Abbott et al., 2018a; Thomas et al., 2019). Though the sub-watersheds of the Couesnon and Rance watersheds are geographically close, they span the Brittany-wide range of observed land use and watershed characteristics (Table S1).

Conceptual Approach

Nutrient retention and removal (hereafter “attenuation”) involve multiple hydrological and biogeochemical processes that are difficult to characterize because many of them are not directly observable due to long timescales or inaccessibility (e.g., groundwater processes) (Aquilina et al., 2018; Kolbe et al., 2019), 3-dimensional variation in soil characteristics (Sebilo et al., 2013; Musolff et al., 2015), and nutrient legacies (Van Meter and Basu, 2017; Ehrhardt et al., 2019). Consequently, to identify the ecological drivers of nutrient attenuation at watershed scales, we selected tracers or proxies that could be associated with hydrological flowpath, residence time, and

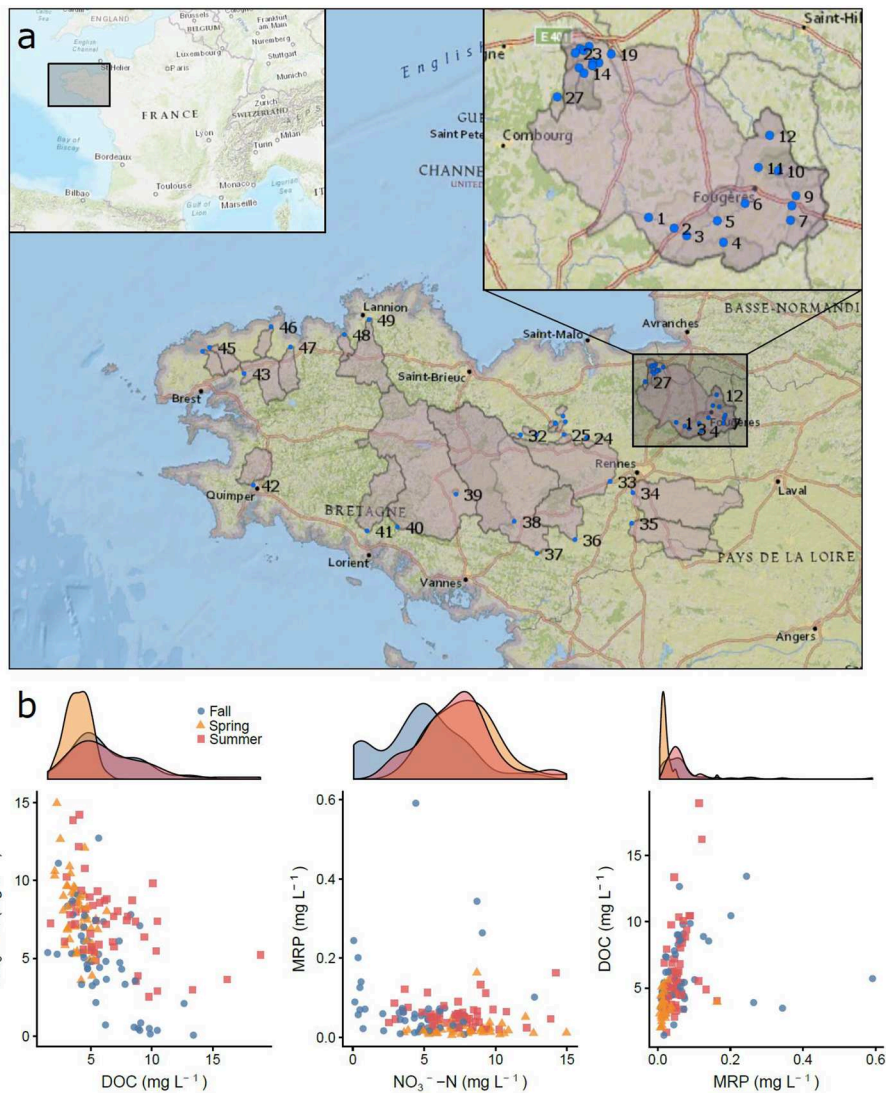

FIGURE 2 | (a) Location of the 49 watersheds sampled during the 3 field campaigns (November 2015, March 2016, and June 2018) in Brittany, France. The Couesnon watershed is enlarged to show the 23 nested watersheds in greater detail. (b) Distribution of nutrient concentrations for dissolved organic carbon (DOC), nitrate (NO_3^-), and Molybdate-Reactive Phosphorus (MRP). Density plots above the Cartesian planes show seasonal shifts in nutrient concentrations along the x-axis.

biogeochemical reactions (Pinay et al., 2015; Abbott et al., 2016). Informed by the ecological control points concept, which assesses reaction rates in a spatiotemporal context (McClain et al., 2003; Bernhardt et al., 2017); and the Damköhler approach which assesses overall attenuation capacity (Ocampo et al., 2006; Oldham et al., 2013), we attempted to quantify biogeochemical and hydrological controls of N and P attenuation at watershed scales with a crossed-proxy approach (Abbott et al., 2016). We were particularly interested in why relationships between land use and stream nutrient concentrations and fluxes often break down at small scales (Burt and Pinay, 2005; Heathwaite, 2010), and how well watershed characteristics and easily measured proxies could predict nutrient attenuation and shine light on the relative importance of surface and subsurface attenuation

processes (Ben Maamar et al., 2015; Dupas et al., 2019a; Kolbe et al., 2019) and hydrological time lags in soils, sediments, and aquifers (Thomas et al., 2012; Sebilo et al., 2013; Van Meter et al., 2016). To address these questions, we used a diverse set of physicochemical parameters described in detail in the **Supplementary Information (SI: Proxy Toolbox)** and briefly outlined below (Figure 1).

Proxies of Hydrological Residence Time and Flowpath

We used (REEs, dissolved silica (DSi), and Radon-222 as proxies of where water went as it passed through the watershed, what conditions it experienced, and how long it stayed there (SI: Proxy Toolbox). The dissolved REE signature of water is initially

set by the bedrock, but redox conditions can cause selective changes (Dia et al., 2000; Gruau et al., 2004). Specifically, cerium (Ce) readily oxidizes to Ce^{+4} and precipitates in the presence of oxygen (Moffett, 1990; De Carlo et al., 1997; Braun et al., 1998), creating a negative Ce anomaly in water that has experienced consistently oxidizing conditions (Gruau et al., 2004; Pinay et al., 2015). Because redox conditions and organic matter availability strongly influence N and P attenuation processes (e.g., denitrification; P adsorption by Fe-oxyhydroxides) (Stumm and Sulzberger, 1992; Pinay et al., 2015; Gu et al., 2019), we tested the relationship between the Ce anomaly of stream waters with nutrient attenuation at watershed scales. To assess water residence time, we used DSI concentration, which has been found to strongly correlate with subsurface residence time in many hydrogeological contexts (Ayraud et al., 2008; Marçais et al., 2018). Our DSI estimates of residence time, calculated using the empirical relationship derived in Marçais et al. (2018), agreed with estimates derived from chlorofluorocarbons (CFCs) and other dissolved gases from other studies in this region (Molénat et al., 2013; Ben Maamar et al., 2015; Kolbe et al., 2016). Radon-222 (^{222}Rn) is another tool to constrain groundwater-surface water interactions (Bertin and Bourg, 1994; Cable et al., 1996; Stieglitz et al., 2010). A product of natural radioactive decay in igneous bedrock, ^{222}Rn has a half-life of 3.82 days, making it an ideal tracer of deep flowpaths (Oyarzún et al., 2014). Because deep and long flowpaths increase the likelihood of encountering redox conditions suitable for N removal pathways such as denitrification, we measured ^{222}Rn concentration in all stream water samples.

Proxies of Biogeochemical Transformation

To assess the degree of biogeochemical attenuation of nutrients and the relative importance of nutrient loading vs. nutrient removal, we quantified stable isotopes of NO_3^- ($\delta^{15}N$ and $\delta^{18}O$), optical characteristics and biodegradability of dissolved organic matter (DOM), and nutrient stoichiometry (SI: *Proxy Toolbox*). Stable isotopes can indicate nutrient source and degree of biogeochemical processing (Mariotti et al., 1981; Lehmann et al., 2003; Malone et al., 2018). NO_3^- isotopes are particularly useful because NO_3^- is a dominant form of nitrogen in nutrient saturated ecosystems (Aber et al., 1998), organic and industrial fertilizers have distinct initial $\delta^{15}N$ and $\delta^{18}O$ (Bedard-Haughn et al., 2003; Lohse et al., 2013; Denk et al., 2017), and denitrification (both heterotrophic and autotrophic) strongly fractionates NO_3^- isotopes, enriching the residual $\delta^{15}N$ and $\delta^{18}O$ (Ayraud et al., 2006; Hosono et al., 2014; Malone et al., 2018). Therefore, we predicted that watersheds with isotopically-enriched NO_3^- would have higher N attenuation (Lehmann et al., 2003) or alternatively that they would have primarily organic fertilizer (Bedard-Haughn et al., 2003).

We used multiple characteristics of DOM to assess the degree of biogeochemical processing, nutrient source, and multi-elemental interactions. DOM has been described as a master variable that influences multiple nutrient cycles (e.g., it is a major source of inorganic N and P in nutrient-poor ecosystems) and general physicochemical conditions (McDowell, 2003; Zarnetske et al., 2018). DOM consists of dissolved organic carbon (DOC),

N, P and other nutrients in molecular forms ranging from complex organic molecules to simple compounds. The molecular composition of the DOM influences its biodegradability and photoreactivity, affecting its persistence in the ecosystem and influence on nutrient cycles (Wymore et al., 2018; Harjung et al., 2019). In addition to biodegradability incubations (details below), we calculated two optical proxies of DOM composition: specific ultra-violet absorbance at 254 nm ($SUVA_{254}$) and the spectral ratio (S_R) of slopes within the 275–290 and 350–400 nm range (Weishaar et al., 2003; Helms et al., 2008; Vonk et al., 2015). DOM concentration and characteristics can also indicate hydrological flowpaths because DOM is less abundant and more microbially altered in groundwater (Shen et al., 2015; Mu et al., 2017; Coble et al., 2019).

Nutrient stoichiometry, which is based on conservation of mass and constant proportions in many organisms, allows prediction of retention or release of different compounds based on availability and relative demand (Sterner and Elser, 2002; Allen and Gillooly, 2009; Helton et al., 2015). We used nutrient ratios as metrics of flowpath and biogeochemical transformation. For example, a negative relationship between DOC and NO_3^- has been widely observed in freshwater and estuarine ecosystems (Sterner and Elser, 2002; Taylor and Townsend, 2010; Stubbins, 2016). This relationship has been primarily attributed to stoichiometric controls, where abundant DOC promotes NO_3^- removal via denitrification since DOC is the most common electron donor and in high-DOC watersheds oxygen could be depleted more rapidly due to mineralization of DOC, resulting in more anoxic zones where denitrification can occur (Arango et al., 2007; Fork and Heffernan, 2013; Helton et al., 2015). Alternatively, the negative relationship between DOC and NO_3^- could simply be caused by a negative correlation between sources, where watersheds that favor deeper hydrological flowpaths have a carbon-poor and nitrogen-rich signal (Abbott et al., 2018b). Therefore, we predicted higher nutrient attenuation in catchments with greater DOC: NO_3^- ratios.

Hydrograph Metrics

The characteristics of river flow can indicate fundamental hydrological properties at watershed scales (Fang and Shen, 2017; Moatar et al., 2017). Higher peak flows during storm events can indicate greater near-surface runoff, while less responsive hydrographs and higher base flows between events can indicate longer residence time and greater proportion of subsurface flow (Feijóo et al., 2018; Kirchner, 2019). In this context, we calculated several, non-redundant hydrological metrics (see **Table S2**) based on daily stream flow: (i) the mean, (ii) coefficient of variation, (iii) skewness, (iv) kurtosis, (v) the autoregressive lag-one correlation coefficient (AR1), (vi) the amplitude, (vii) the phase of the seasonal signal (Archfield et al., 2014), and (viii) the W2. The W2 is an index of hydrologic reactivity that is the percentage of annual discharge that occurs during the highest 2% of flows (Walsh and Lawler, 1981; Moatar et al., 2013, 2017).

Field and Laboratory Analysis

To quantify the proxies described above, we collected water samples and measurements from 49 watersheds throughout

Brittany, France (Figure 2). We selected the 49 sites based on accessibility, availability of historical data (nutrient input and export chronicles and land-use data), and to cover a range of watershed sizes. Field campaigns were in early November of 2015, late March of 2016, and late June of 2018.

At each site, we collected one 5-L sample of stream water for immediate sensor readings and eight smaller samples for laboratory analyses. From the first sample, we used a handheld multiparameter probe (YSI, incorporated; Yellow Springs, USA) to measure dissolved oxygen, redox, pH, temperature, and turbidity. We determined $SUVA_{254}$ and S_R from the same sample with a field-deployable spectrophotometer (s::can; Vienna, Austria). For the lab analyses, we immediately filtered subsamples using a 50 mL syringe and two 250 mL filter towers. We used a 0.2 μm cellulose acetate syringe filter to prepare samples for the analysis of cations, REEs, and NO_3^- isotopes. For the first filter tower, we used a 0.45 μm cellulose acetate filter to prepare samples for Molybdate-Reactive Phosphorus (MRP), anions, and DOC analysis. For the second tower, we used a 0.7 μm glass fiber filter, which removes most particulates but allows many bacteria to pass (Vonk et al., 2015), to prepare samples for the biodegradable DOC (BDOC) bioassay experiment. All filters, towers, and syringes were pre-rinsed with de-ionized water and flushed with sample prior to collecting final samples. We also collected an unfiltered, bubble-free 200 mL sample for ^{222}Rn analysis. These samples were analyzed for ^{222}Rn within 12 h of sampling using a radon detector (DurrIDGE RAD7 analyzer, Billerica, USA), with most samples analyzed immediately in the field. Delayed samples were adjusted for time lags to correct ^{222}Rn decay. The ^{222}Rn values for the spring sampling were lost due to operator error.

MRP concentrations were determined colorimetrically via reaction with ammonium molybdate (Murphy and Riley, 1962), with a precision of $\pm 4 \mu\text{g l}^{-1}$ (Gu et al., 2018). Nitrate isotope samples were frozen immediately and shipped to the UC Davis Stable Isotope Facility for analysis of $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ of NO_3^- by bacterial denitrification assay (McIlvin and Casciotti, 2011). Isotope ratios of $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ were measured using a ThermoFinnigan GasBench + PreCon trace gas concentration system connected to a ThermoScientific Delta V Plus isotope-ratio mass spectrometer (Bremen, Germany) with a precision of $\pm 0.4\text{‰}$ and 0.5‰ for $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$, respectively. Cations and REE samples were analyzed by inductively coupled plasma mass spectrometry (ICP-MS; Agilent 7700x, Santa Clara, USA). Calibration curves and accuracy controls were performed following best practices (Yeghicheyan et al., 2013), using river water reference material for trace elements with a wide compositional range (SLRS-5, National Research Council of Canada). De-ionized water purified with a Milli-Q (Millipore, Darmstadt, Germany) system was used for blanks. Total relative uncertainties were $\pm 5\%$.

We conducted BDOC bioassay experiments using four replicates of 100 mL aliquots of filtered stream water for each site and incubated in a dark incubation chamber for 28 days at 20°C (Vonk et al., 2015). We sampled each replicate at the beginning (t_0) and end of the incubation (t_{28}). The t_0 samples

were acidified with 6M HCl to a pH of 2 and stored in the refrigerator at 4°C until the t_{28} sampling. After the t_{28} samples were acidified, the t_{28} and t_0 samples were analyzed together for DOC (Shimadzu TOC-5050A, Kyoto, Japan, precision $\pm 5\%$) within 1 week. We calculated the percent BDOC for each sample using the following equation:

$$\%BDOC = \frac{DOC_{t_0} - DOC_{t_{28}}}{DOC_{t_0}} * 100\% \quad (1)$$

where DOC_{t_0} and $DOC_{t_{28}}$ are the concentrations of DOC at t_0 and t_{28} . We reported the mean of the 4 replicates as the overall BDOC value per sampling for each site.

Watershed Characteristics and Nutrient Trends

To test how climate and landscape characteristics affect nutrient attenuation, we delineated all watersheds using ArcMap (ESRI) and extracted landscape characteristics including vegetation cover, land use, bedrock type, river network density, and flow regulation. Mean annual temperature and precipitation were downloaded from the WorldClim database (Fick and Hijmans, 2017) using the “raster” package in R (Version 3.5.2; R Core Team, 2018). To obtain long-term nutrient and hydrological discharge data, we selected monitoring stations using the “Near” tool in ArcMap. We obtained long-term data for 27 of the 49 watersheds and calculated annual runoff, nutrient flux, and attenuation for those 27 watersheds using 10 years of flow and water chemistry data (NO_3^- and TP) from July 2008–July 2018. We calculated the eight flow metrics described above from the flow time series using the EflowStats R package.

We calculated mean annual specific discharge by averaging the flow per year and dividing by watershed area. We calculated N and P fluxes exported from the watershed using the discharge-weighted concentration method (Moatar et al., 2013; Raymond et al., 2013):

$$Flux = k * \bar{Q} * \frac{\sum_i C_i * Q_i}{\sum_i Q_i} \quad (2)$$

where C_i and Q_i represent concentration and runoff at the time of sampling, \bar{Q} is mean annual runoff, and k is a conversion factor to obtain fluxes in $\text{kg N or P ha}^{-1} \text{ yr}^{-1}$. We calculated apparent attenuation of NO_3^- and TP using the following mass-balance equation:

$$Attenuation = 1 - \frac{Flux}{Surplus} \quad (3)$$

where Flux is calculated as described above (Equation 2) and Surplus is the watershed-specific nutrient surplus based on fertilizer inputs and crop yields (Poisvert et al., 2017; Dupas et al., 2018).

Because not all watersheds had nearby water quality and discharge stations, we calculated another metric of nutrient attenuation: the residuals from a regression of NO_3^- or TP concentration against percent agricultural cover. While this

metric is much coarser than the mass-balance estimates of attenuation (Equation 3), it provided an independent metric of attenuation that was quantifiable even for watersheds without discharge and long-term data. Additionally, it allowed calculation of seasonal dynamics in the relationship between land use and nutrient concentration, whereas the mass-balance-based nutrient attenuation metric provided a single value derived from the entire decadal time series. We reasoned that because most nutrient inputs in this region come from agricultural activity, watersheds with nutrient concentrations above the trend line would be less attenuative and points below the line would be more attenuative, comparatively to the average data set (Figure 3). We used NO_3^- concentration for these calculations because it accounted for 92% of measured total N, and TP to account for all measured P (Figure S2).

One weakness of both the mass-balance and residual metrics of nutrient attenuation is that apparent attenuation can occur if significant time lags exist between nutrient inputs and export (Basu et al., 2011; Ehrhardt et al., 2019). Over the past two decades, agricultural practices have improved and many nutrient point sources have been eliminated in western France (Poisvert et al., 2017; Abbott et al., 2018b; Dupas et al., 2018), and we reasoned that the slope of the decline in nutrient concentration would be negatively correlated with hydrological nutrient legacy (i.e., watersheds with more groundwater and soil nutrient storage would have slower rates of nutrient decrease after inputs ceased or were reduced). For the 27 watersheds with long-term data, we calculated Theil-Sen slope estimates using the Siegel method, which provides an estimate of change through time that is highly robust to extreme values due to real variability (e.g., during high or low flows) or analytical errors (Abbott et al., 2018b). We correlated these slope estimates with the nutrient attenuation metrics to assess how much of the apparent attenuation could be due to hydrological

nutrient legacy rather than more permanent removal and retention processes.

Quantifying Spatial Stability and Identifying Drivers of Nutrient Attenuation

We determined the persistence of spatial patterns through time for proxies and water chemistry across watersheds using the spatial stability concept (Abbott et al., 2018a; Dupas et al., 2019b). The Spearman rank correlation between each pair of sampling dates for each parameter indicates how much of the spatial structure is preserved through time. Spatial stability of water chemistry can result from high spatial variability and synchronous temporal variability (Abbott et al., 2018a; Dupas et al., 2019b).

To disentangle the controls on nutrient attenuation, we regressed each proxy against nutrient attenuation (mass balance and residuals) and fluxes. We used pairwise correlation and multiple linear regression (MLR) to identify which proxies were the most closely associated with nutrient attenuation. Because many of the proxy data were not linearly related with attenuation and fluxes, we used Spearman correlations to quantify the strength of relationships. For the MLR models we grouped predictors into two categories: biogeochemical proxies and hydrological and watershed characteristics (hereafter referred to as the proxy and hydro models, respectively). To test our hypotheses about controls on nutrient attenuation, we categorized each predictor based on whether it was most associated with hydrological and watershed characteristics or biogeochemical reactions (Figure 1, Table 1). We standardized all predictors (mean = 0 and standard deviation = 1) to allow comparison of parameter coefficients as a measure of relative contribution to model prediction of the response variable (nutrient mass balance estimates), and we checked for multicollinearity among predictors using the variance

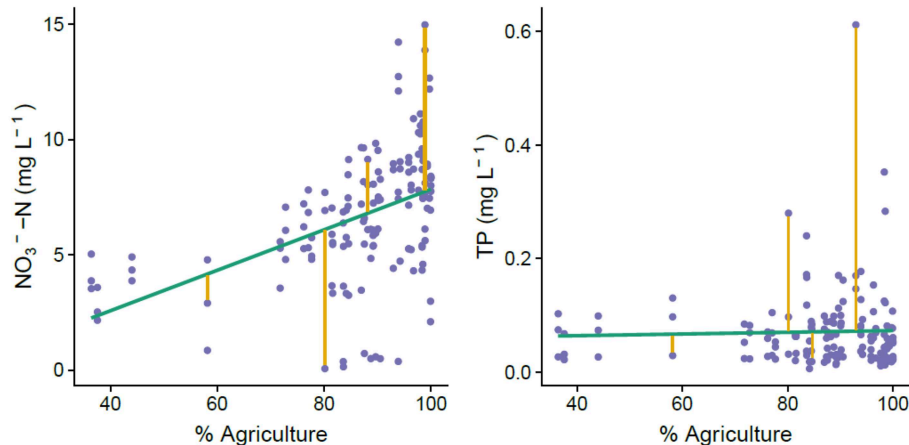

FIGURE 3 | Visualization of how we calculated residuals in the relationship between agricultural land use and nutrient concentrations for each catchment. Because agriculture is the predominant nutrient source in the Brittany region, we used departure from the relationship between agriculture and nutrient concentration as a metric of nutrient attenuation capacity. Points above the regression line represent less attenuation capacity because there is more nutrient in the system than would be expected with this rough estimate of nutrient inputs.

inflation factor (Abbott and Jones, 2015). We ran the models for each category (i.e., proxy and hydro models) and selected the most parsimonious model for each by stepwise regression. Though model selection techniques continue to be controversial in ecology (reviewed in Malone et al., 2018), our primary goal was to assess relative influence of the major predictors. As such, we simply discuss the overall trends (e.g., what parameters appeared repeatedly in multiple models) of individual and multiple regression results (Tables 2, 3) and we abstain from interpreting the inclusion or exclusion of less influential predictors.

RESULTS

Nutrient Context and Spatial Stability of Water Chemistry

The three samplings captured distinct hydrological conditions, with low but variable discharge among sites in the fall sampling (November of 2015), highest discharge in the spring (March of 2016), and low and consistent discharge among sites in the summer (June of 2018; Figure S1). Nutrient concentrations and stoichiometry varied substantially across the watersheds and through time (e.g., 0–15 mg L⁻¹ of N-NO₃⁻ and 0–0.6 mg L⁻¹ of MRP). We observed a negative relationship between DOC and NO₃⁻ and a positive relationship between DOC and MRP, which varied somewhat seasonally (Figure 2b, Figure S1). Inorganic forms of N and P dominated total concentrations for these nutrients across watersheds, with NO₃⁻ making up 93% of total N and MRP making up 74% of TP (Figure S2).

For the 27 watersheds with decadal nutrient concentration data on a monthly time step, the long-term trends were fundamentally different for C, N, and P (Figure 4). Theil-Sen slope estimates for DOC concentration indicated slight increases through time for 75% of the watersheds, decreases for NO₃⁻

concentration for all but three watersheds, and no change for PO₄³⁻ and TP concentrations (Figure 4).

Spatial stability (persistence of spatial rankings through time) varied substantially among proxies and solutes (Figure 5). Conductivity, δ¹⁵N, TP, DSI, and many major ions showed high spatial stability (i.e., more than half the spatial pattern among the three sampling dates was preserved; ρ > 0.7). All the DOM properties, ²²²Rn, O₂, temperature, and NO₂⁻ showed very low stability (i.e., ρ < 0.4) indicating substantial seasonal and potentially interannual variability, with the rest of the parameters showing moderate stability (Figure 5).

Differences in Attenuation and Fluxes in Agricultural Watersheds

Median nutrient attenuation as calculated by mass balance was 58.1% for N and 98.6% for P across the watersheds. N and P mass balance results were weakly correlated (R² = 0.18, p < 0.001), indicating that watersheds with high attenuation for N tended to also have high attenuation for P (Figure 6). Results for N mass balance showed substantially higher variability than P mass balance, ranging from -2 to 88.4% for N but only 96.1 to 99.5% for P. As another estimate of nutrient attenuation, we calculated the residuals of the regression of percent agricultural cover and measured NO₃⁻ and TP concentrations (Figure 3). N-NO₃⁻ was significantly correlated with agricultural cover (R² = 0.21, p < 0.001) and residuals from that relationship ranged from -7.23 to 6.93 mg L⁻¹ with a median of -0.37 mg L⁻¹. TP was not significantly correlated with agricultural cover (R² = 0.001, p = 0.70) and residuals from that non-significant relationship ranged from -0.54 to 0.047 mg L⁻¹ with a median of 0.016 mg L⁻¹. N residuals showed a weak, positive correlation with N mass balance estimates (R² = 0.15, p < 0.001; Figure 6), but we observed no relationship between P residuals and P mass balance (Figure 6).

N fluxes varied by an order of magnitude (6.1–64 kg N ha⁻¹ yr⁻¹) and were negatively correlated with mass balance estimates

We considered models with 1–6 predictors and bolded the most parsimonious model in each category based on AIC. All predictors were standardized (mean = 0 and standard deviation = 1) to allow comparison of parameter coefficients as a measure of relative contribution to model prediction of the response variable (greater absolute value means more influential). Full models contained all variables within a category (e.g., measured proxies or watershed characteristics calculated or extracted from GIS) and the most parsimonious model (emphasized in bold) was chosen using the Akaike information criterion (AIC).

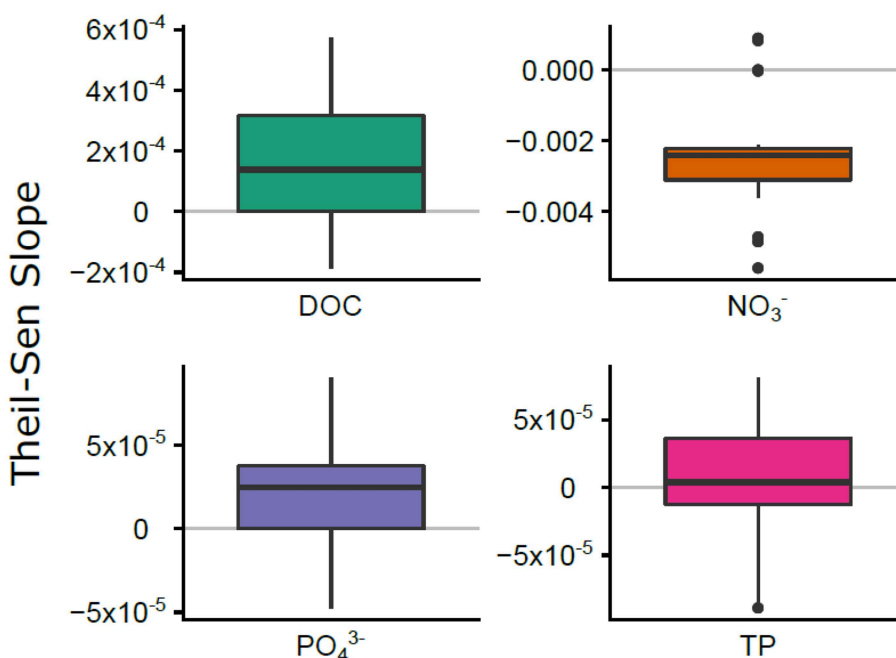

FIGURE 4 | The distribution of Theil-Sen nutrient slopes for C, N, and P for the 27 watersheds with long-term nutrient data. Horizontal gray lines indicate zero slope (no temporal trend).

($R^2 = 0.73, p < 0.001$), with fluxes increasing as mass balance estimates decreased (Figure 6). P fluxes varied by a factor of 4 (0.17–0.69 kg P ha⁻¹ yr⁻¹) and were negatively correlated with P mass balance ($R^2 = 0.36, p < 0.001$), but there was no relationship with P residuals.

Individual Predictors of Nutrient Attenuation

Based on the pairwise Spearman correlations with hydrological parameters, annual runoff was strongly negatively correlated with the N and P mass balance estimates ($\rho = -0.89$ and -0.41 , respectively), and the hydrological reactivity index (W2) was

strongly positively correlated with N and P mass balance ($\rho = 0.60$ and 0.32 , respectively). For biogeochemical proxies, N mass balance estimates was correlated with $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$, ^{222}Rn , Ce/Ce^* , and $\text{DOC}:\text{NO}_3^-$ stoichiometry ($\rho > |0.40|$) and had a weaker relationship with SUVA_{254} ($\rho = -0.27$; Figure 7). N residuals showed similar results for $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ ($\rho > 0.40$) but had a much weaker relationship with ^{222}Rn , a much stronger relationship with $\text{DOC}:\text{NO}_3^-$ ($\rho = -0.20$ and 0.71 , respectively), and no significant relationship with Ce/Ce^* or SUVA_{254} . N fluxes showed similar but opposite relationships as attenuation, and a weak relationship with DSi was also observed ($\rho = 0.23$). P mass balance estimates was positively correlated

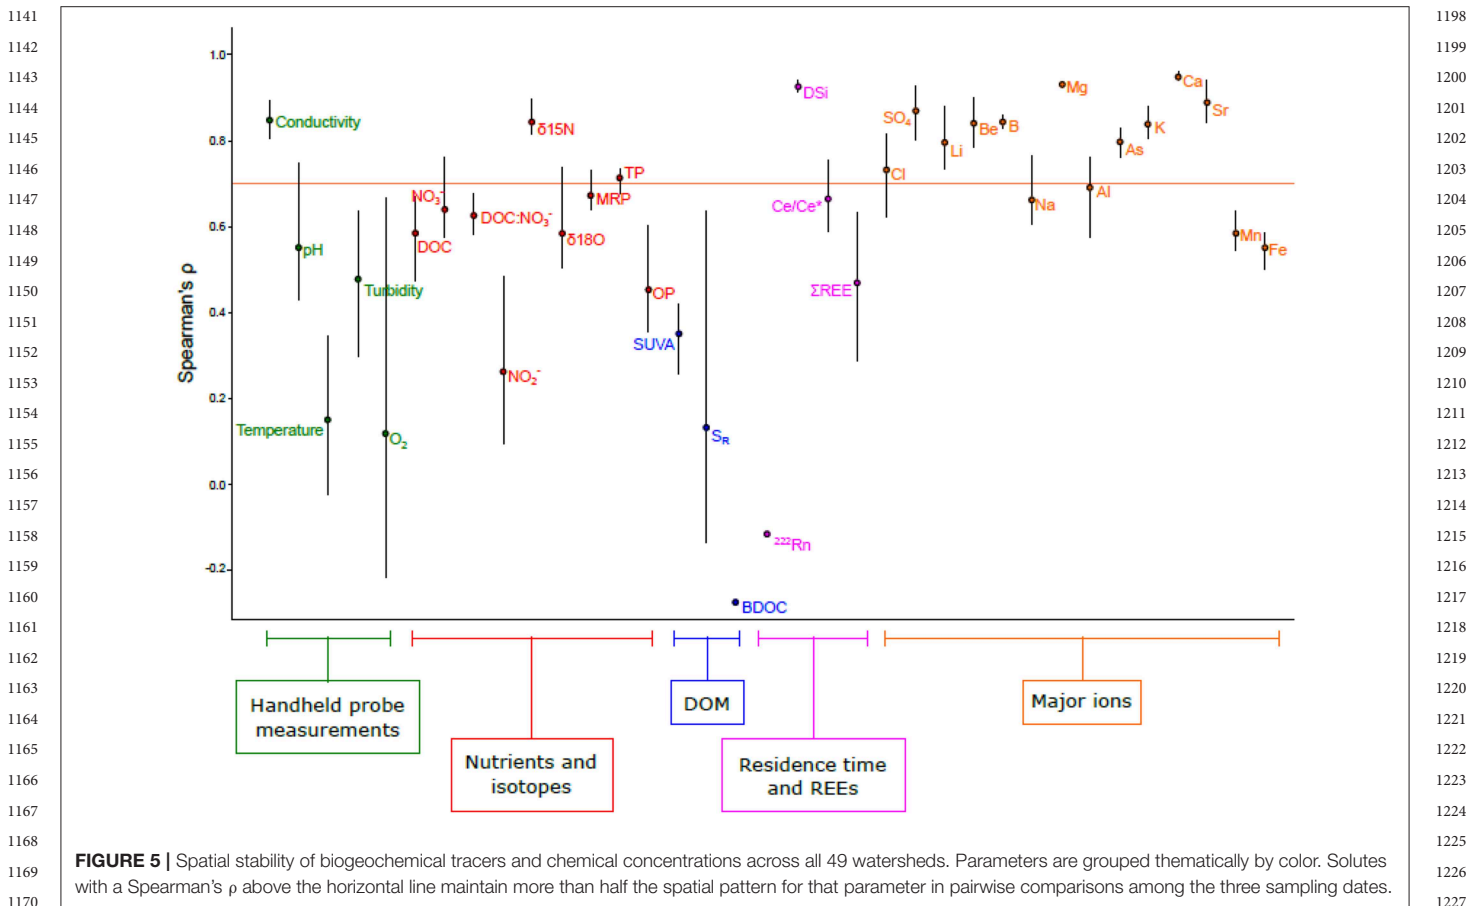

FIGURE 5 | Spatial stability of biogeochemical tracers and chemical concentrations across all 49 watersheds. Parameters are grouped thematically by color. Solutes with a Spearman's ρ above the horizontal line maintain more than half the spatial pattern for that parameter in pairwise comparisons among the three sampling dates.

with $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ ($\rho = 0.41$ and 0.29 , respectively; **Figure 8**) and negatively correlated with ^{222}Rn ($\rho = -0.35$). P residuals were strongly negatively correlated with $\delta^{15}\text{N}$ and ^{222}Rn ($\rho = -0.52$ and -0.44 , respectively) and had weaker relationships with $\delta^{18}\text{O}$, Ce/Ce^* , and S_R ($\rho < |0.25|$). The P fluxes had similar but opposite relationships with the same proxies as attenuation, in addition to a negative relationship with DOC:NO_3^- ($\rho = -0.40$).

To test how nutrient legacy could be related to apparent nutrient attenuation, we correlated the decadal Theil-Sen concentration slopes (**Figure 4**, **Figure S3**) with estimates of nutrient attenuation. N mass balance estimates and residuals were positively correlated with decadal trends for NO_3^- , indicating that the watersheds experiencing the slowest decreases in NO_3^- through time tended to have higher apparent attenuation ($R^2 = 0.17$ and 0.10 , respectively, $p < 0.05$; **Figure S3**). N flux was negatively correlated with decadal NO_3^- trends, indicating that watersheds with faster decreases in NO_3^- had higher N fluxes ($R^2 = 0.25$, $p < 0.05$). PO_4^{3-} slopes were positively correlated with P mass balance estimates ($R^2 = 0.15$, $p < 0.05$), indicating that the watersheds with the slowest decreases or greatest increases in PO_4^{3-} had higher apparent P attenuation, but PO_4^{3-} slopes were not significantly correlated with P residuals. TP fluxes were negatively correlated with NO_3^- trends ($R^2 = 0.27$, $p < 0.05$).

Multiple Linear Regression Models of Nutrient Attenuation

For the hydro MLR models (only hydrological and watershed characteristics parameters), the models with only one predictor explained 91% of the variance explained by annual runoff for N mass balance estimates and 62% of the variance explained by the abundance of schist bedrock for P mass balance (see **Tables 2, 3**). The most parsimonious (based on AIC) hydro model for N mass balance estimates also included other hydrological and land use variables (e.g., mean annual flow and amplitude, and % artificial land cover, wetlands, and stream length), which slightly enhanced the model performance (adjusted $R^2 = 0.94$, $\Delta\text{AIC} = 12.19$). For P mass balance estimates, the initial hydro model (i.e., only relative abundance of schist) was improved by adding river density (adjusted $R^2 = 0.62$, $\Delta\text{AIC} = 4.84$). The final hydro model results are shown in **Figure 9**.

The proxy MLR models that used biogeochemical proxies to predict attenuation did not explain as much variance as the hydro models, but they indicated other processes besides runoff and bedrock type that are important drivers of attenuation. For example, the single most important proxy for N was $\delta^{15}\text{N}$, which accounted for 37% of the variation in N mass balance estimates. However, the most parsimonious model

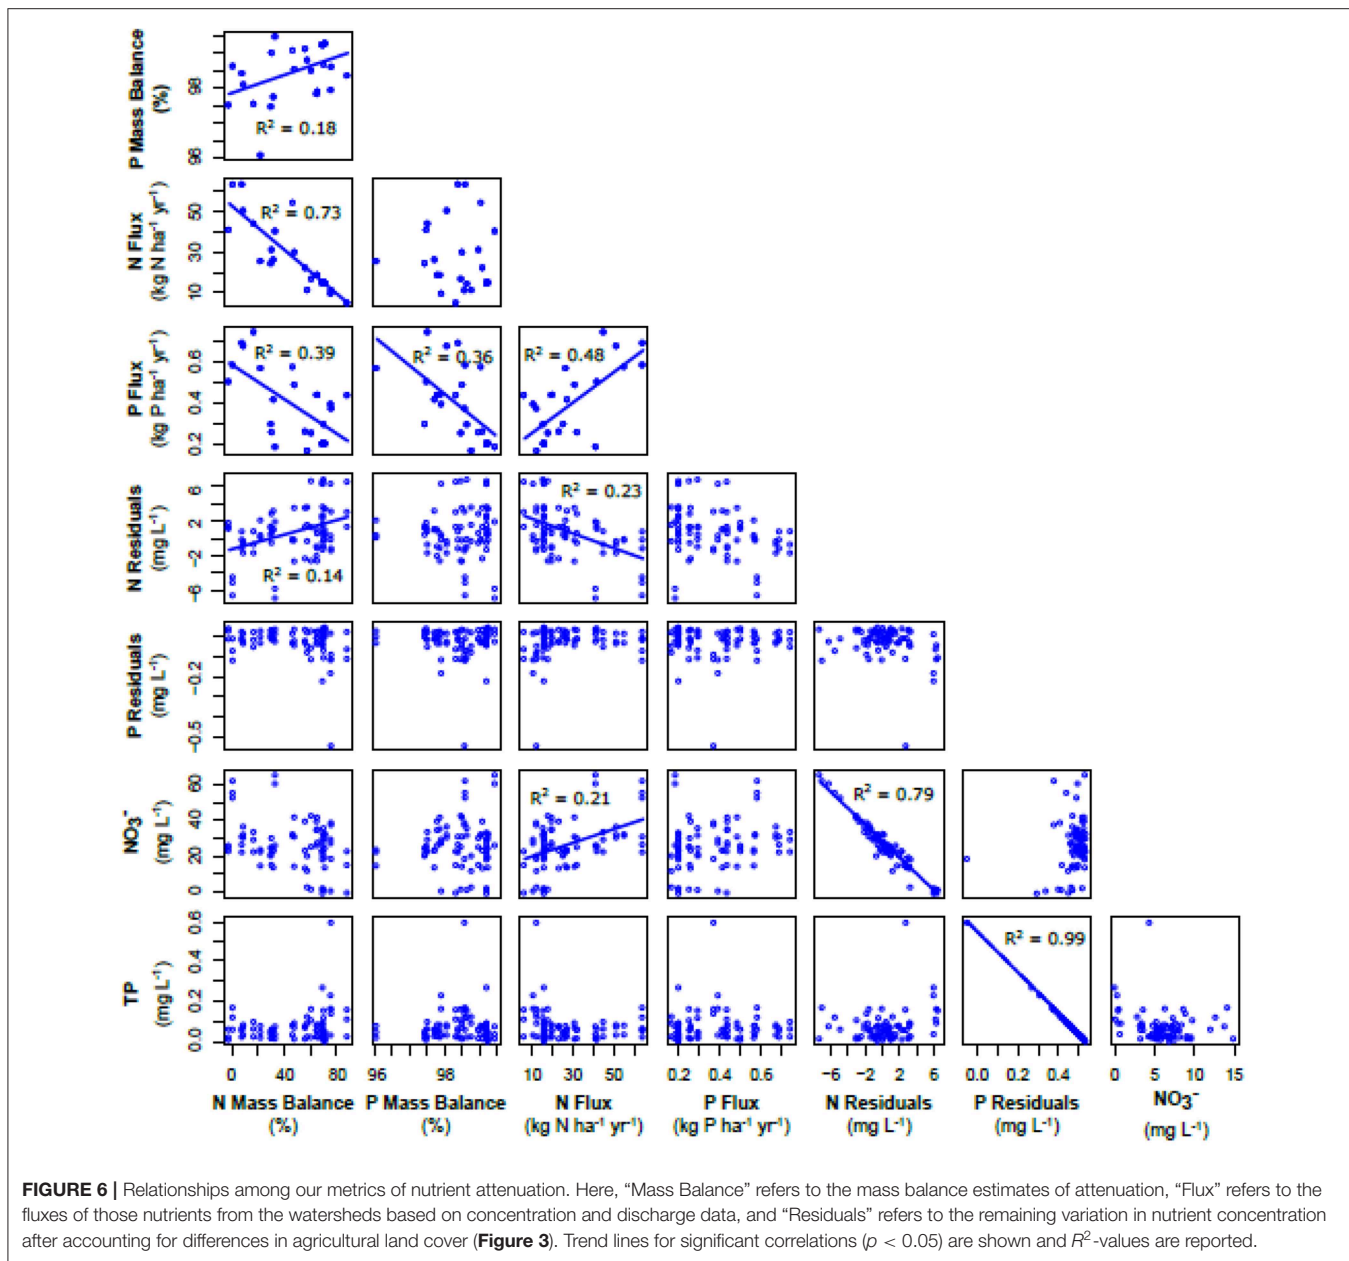

FIGURE 6 | Relationships among our metrics of nutrient attenuation. Here, “Mass Balance” refers to the mass balance estimates of attenuation, “Flux” refers to the fluxes of those nutrients from the watersheds based on concentration and discharge data, and “Residuals” refers to the remaining variation in nutrient concentration after accounting for differences in agricultural land cover (Figure 3). Trend lines for significant correlations ($p < 0.05$) are shown and R^2 -values are reported.

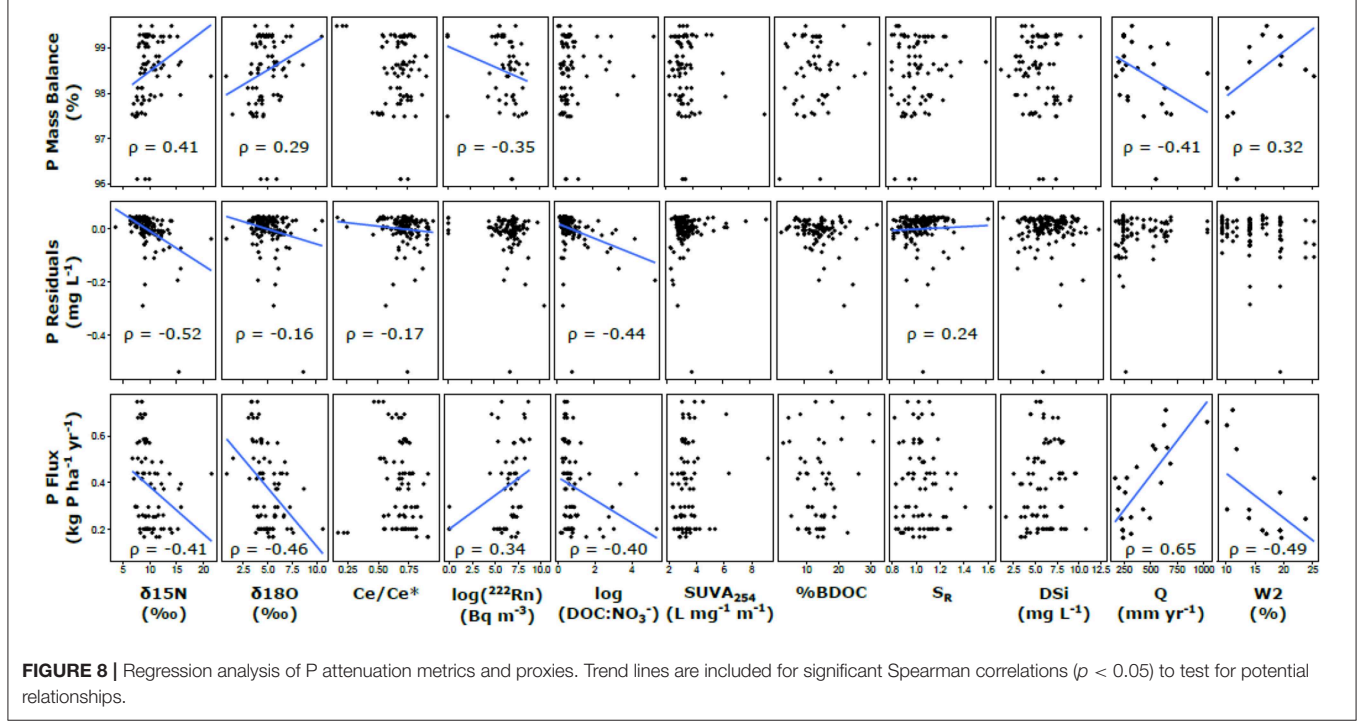

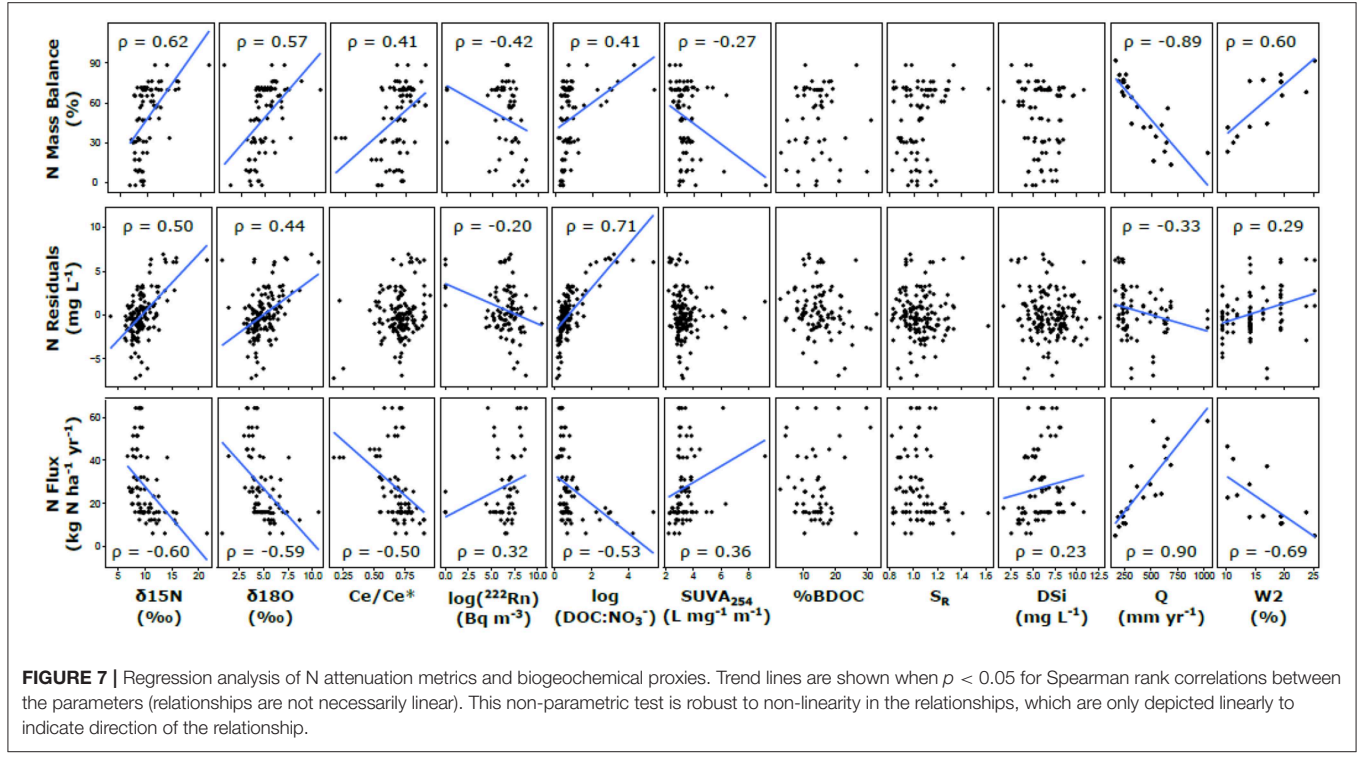

included 5 other proxies (ΣREE , ^{222}Rn , Ce/Ce^* , $\delta^{18}\text{O}$, and turbidity), together accounting for 75% of the variation in N mass balance estimates. For P mass balance estimates, the single most important proxy was also $\delta^{15}\text{N}$, accounting for 9% of the variation. However, the most parsimonious model included 4 other proxies (ΣREE , S_R , ^{222}Rn , and Ce/Ce^*), together explaining 27% of the variation in P mass balance estimates. Furthermore, the shared proxies between N and P attenuation models (e.g., $\delta^{15}\text{N}$, ΣREE , ^{222}Rn , and Ce/Ce^*) had surprisingly similar relationships in both direction and magnitude, apart from Ce/Ce^* which had a positive relationship with N mass balance estimates and a negative relationship with P mass balance estimates. Proxy model results are shown in Figure 9.

DISCUSSION

We hypothesized that hydrological properties, surface and subsurface characteristics, and biogeochemical conditions would interact to determine nutrient attenuation at watershed scales. Based on our analysis of 49 watersheds, 27 of which had long-term nutrient and discharge estimates, hydrological properties set the initial attenuation capacity, with secondary effects from biogeochemical conditions and land-use parameters. These results corroborate findings from other regions where runoff strongly controls nutrient attenuation and flux (Covino et al., 2010; Zarnetske et al., 2018; Ehrhardt et al., 2019). However, we point out that runoff is a high-level parameter that interacts with other hydrological metrics, watershed

characteristics, and biogeochemical reactions at multiple spatiotemporal scales. Below, we discuss how runoff influences and is influenced by many ecological dynamics including

long-term nutrient legacies, redox conditions, and land use, and how this could inform our local and global efforts to solve eutrophication.

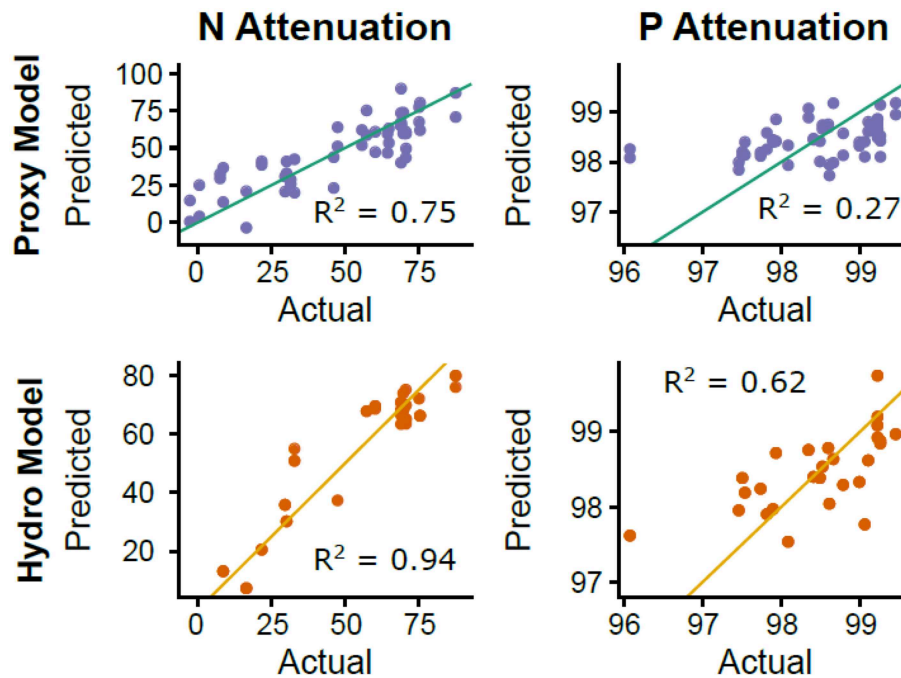

FIGURE 9 | N and P attenuation (based on mass balance estimates reported as percentages) predicted by hydrological and watershed characteristics, and biogeochemical proxies. The “hydro” model included hydrological and watershed characteristics and the “proxy” model included biogeochemical proxy data from the three field campaigns (see **Table 2**).

Tradeoffs Between Nutrient Attenuation and Nutrient Recovery

At larger spatiotemporal scales, untangling proximate and ultimate drivers of nutrient flux and attenuation is exceedingly difficult because socioecological systems co-evolve based on shared and dynamic conditions (Thomas et al., 2015; Bogaart et al., 2016; Malone et al., 2018). Consequently, at medium to large scales, many risk factors for nutrient flux are co-linear, including climate, land use, soil type, ecosystem stature, and flow regime (Knoben et al., 2018; Lin et al., 2019; Smits et al., 2019). This has been observed within the boundaries of our study region, where agriculture tends to be more intense in areas underlain with micaschist, which is better suited for mechanical agriculture, but also more prone to nutrient export because of its soil and topographic properties (Thomas et al., 2015).

Of all the hydrochemical parameters we measured, annual runoff had the strongest single relationship with our long-term nutrient attenuation metrics (mass-balance, residuals, and nutrient flux). While this correlation is not surprising for flux, it reinforces a growing understanding that the routing and amount of lateral water flow fundamentally regulates hydrological connectivity and nutrient transport (Dupas et al., 2018; Zarnetske et al., 2018). Perhaps more interestingly, runoff was correlated with long-term trends in nutrient concentration (i.e., rate of nutrient recovery) in our dataset. This means that the high-runoff watersheds that have low nutrient attenuation tend to recover faster when nutrient inputs are decreased. This suggests that hydrological attenuation (Ehrhardt et al.,

2019) is an important contributor to nutrient attenuation in these watersheds. It also makes sense in the context of soil and groundwater nutrient legacies—i.e., a system with more flow can be flushed faster—depending on the ratio between storage and flow (Basu et al., 2011; Van Meter and Basu, 2017; Abbott et al., 2018b). However, this inverse relationship between attenuation and recovery in agricultural watersheds raises the question of whether there is an inevitable tradeoff between nutrient resistance (i.e., nutrient removal capacity) and nutrient resilience (i.e., fast recovery rates; Goyette et al., 2018; Dupas et al., 2019a). Thinking comparatively between the two main nutrients in our study, the higher P attenuation values, which we know are associated with accumulation in soil and sediment rather than permanent removal (Hansen et al., 2002; Sharpley et al., 2013), and the much lower ratio of stock to flux (i.e., watershed P >> annual export of P) suggests that P follows this prediction of high resistance and extremely low resilience (Goyette et al., 2018; Haas et al., 2019).

Subsurface Processes as Key Regulators of Surface Concentrations and Fluxes

Though one valid interpretation of our findings is that hydrological dynamics, especially flow and river network density, dominate nutrient attenuation capacity, several lines of evidence suggest that a more complex range of factors regulates nutrient behavior in these watersheds. Water residence time, a fundamental ecohydrological property (Zarnetske et al., 2011; Kolbe et al., 2016; Thomas et al., 2016) was not associated with

our attenuation metrics nor with recovery rates based on the long-term trends. This is likely because only a portion of the total residence time has the requisite conditions for biogeochemical processes to retain or remove nutrients. This concept, termed *exposure time* (Murphy et al., 1997; Oldham et al., 2013; Pinay et al., 2015), is central to the HotDam framework, because storage or transport in nonreactive zones only affects hydrological attenuation (i.e., time lags; Ehrhardt et al., 2019), not biogeochemical attenuation or removal (Abbott et al., 2016). For example, groundwater denitrification increases with depth in ~80% of watersheds where it has been quantified because of more abundant electron donors in deeper, unweathered bedrock (Kolbe et al., 2019). This dynamic also relates to the previously discussed relationship with runoff, because weathering rates are higher when there is greater water flow through the watershed (Marçais et al., 2018). Greater weathering could depress the vertical horizon where electron donors can sustain denitrification (Kolbe et al., 2019), meaning that higher runoff watersheds not only have shorter residence times, but that their biogeochemical reaction capacity may be lower.

Another indicator that annual runoff is not the sole control of nutrient dynamics is that several biogeochemical proxies associated with deep flowpaths and groundwater were strongly related to both N and P attenuation metrics. Nitrate isotopes, ^{222}Rn , REEs, and $\text{DOC}:\text{NO}_3^-$ were influential proxies of attenuation and fluxes, pointing to the importance of deep flowpaths and anoxia as drivers of nutrient removal (i.e., denitrification) and attenuation via biological and abiotic processes (Gu et al., 2018, 2019; Kolbe et al., 2019). While P is typically not transported through deep groundwater flowpaths because of physicochemical properties (Hansen et al., 2002), P varies systematically with discharge in many catchments with total P often increasing and MRP often decreasing as flow increases (Moatar et al., 2017). Additionally, excess NO_3^- in groundwater can trigger sulfate release and iron oxidation in the presence of pyrite, potentially mobilizing P via links with iron and sulfur in some environments (Smolders et al., 2010; Tang et al., 2016; van Dijk et al., 2019). In watersheds that are discharging their nutrient legacies (i.e., current nutrient loading < historical nutrient loading), NO_3^- concentrations are often higher in groundwater than in near-surface water (Abbott et al., 2018b; Dupas et al., 2018), which could create an indirect link between deep water flow and P attenuation dynamics (Dupas et al., 2015).

A surprising interaction between hydrology and biogeochemistry was the positive relationship between the W2 index (percentage of cumulative discharge that occurs during the highest 2% of daily discharge values) and nutrient attenuation. Contrary to major predictions of ecosystem ecology that nutrient attenuation decreases with hydrological pulses or floods (Fisher et al., 1998; Raymond et al., 2016; Wollheim et al., 2017), the watersheds in this region with higher W2 were relatively more attenuative of nutrients. However, it is important to note that Brittany has temperate hydrology with few floods (Thomas et al., 2019), meaning that the watersheds with relatively higher W2 are still not particularly flashy or hydrologically reactive compared with other regions (Moatar et al., 2013). In this instance, the positive correlation between

nutrient attenuation and the W2 index could be associated with the weathering mechanism described previously (i.e., watersheds with a larger proportion of surface flow vs. groundwater flow could have less weathered and more reactive aquifers; Kolbe et al., 2019) or it could be associated with sediment legacies in and near the river network. In this region and many others, large stocks of nutrient-laden sediments have accumulated in streams, riparian zones, and small reservoirs (Song and Burgin, 2017; Feijóo et al., 2018). These sediments can be important or even primary sources of nutrients, particularly during low flow periods (Dupas et al., 2015; Gu et al., 2018). Watersheds with more powerful or more frequent floods could have flushed out these sediments, effectively increasing net nutrient attenuation by reducing internal loading.

Together, these multi-proxy findings suggest that subsurface characteristics, including hydrological flowpaths and the location of biogeochemical activity, are fundamental to regulating nutrient attenuation and export at watershed scales.

Comparison With Nutrient Attenuation in Different Biomes and Land Use Regimes

The high level of variability in N attenuation that we observed has also been observed in different climatic and anthropogenic contexts. Watersheds in the Northeastern United States have NO_3^- mass balance estimates that range from 9 to 74% (Campbell et al., 2004). While point-source P loading is relatively well-constrained (Kronvang et al., 2007; Grizzetti et al., 2012), watershed-scale estimates of P mass balance remain less common (Withers and Jarvie, 2008; Sharpley et al., 2013; Goyette et al., 2018). In natural ecosystems, P attenuation is often very high, though this varies strongly with ecosystem age and disturbance regime as well as stoichiometric conditions (Vitousek and Reiners, 1975; Verry and Timmons, 1982; Vitousek, 2004; Elser et al., 2007). In contrast, urban watersheds are often extremely leaky to P, with P mass balance estimates ranging from -7 to 74% with a mean of 22% (Hobbie et al., 2017). These urban P losses are attributable to the prevalence of impervious surfaces that decrease residence time, increase flashiness of water flow, and increase fluctuations between oxic and anoxic conditions (Hale et al., 2015, 2016; Blaszcak et al., 2019).

Preventing Rather Than Curing Nutrient Incontinence

The Anthropocene is characterized by concurrent and connected socioecological crises caused by human interference with many of the Earth's biological and abiotic cycles (Vitousek et al., 1997; Steffen et al., 2015; Abbott et al., 2019). Many proposed solutions to these crises seek to manage ecosystem response rather than modify human activity, essentially treating human demand as immutable (Jaggard et al., 2010; Garnier et al., 2014; Abbott et al., 2019). This tendency to cure rather than prevent is particularly prevalent in the fight against eutrophication, where researchers, policymakers, and land managers are going to great lengths to attenuate or remove anthropogenic nutrients in virtually every component of the watershed (Sharpley et al., 2008; Pu et al., 2014; Bol et al., 2018; Wollheim et al., 2018). Given how critical food production is to human wellbeing (Foley et al., 2011; Sutton et al., 2013; Rasul, 2016), these efforts are certainly

1711 justified and some nutrient mitigation practices such as cover
1712 crops, no-till cultivation, hedgerows, and riparian concentration
1713 can improve nutrient attenuation and enhance other ecosystem
1714 benefits (Hansen et al., 2000; Roley et al., 2016; Pinay et al.,
1715 2018; Thomas and Abbott, 2018). However, we believe that
1716 managing ecosystems to enhance nutrient removal will never
1717 solve eutrophication alone. Instead, a growing body of research
1718 suggests that managing human nutrient demand—i.e., reducing
1719 nutrient inputs into the Earth's watersheds—while also protecting
1720 nutrient attenuation capacity across the land to water gradient
1721 is the only comprehensive solution to eutrophication (Garnier
1722 et al., 2014; Bol et al., 2018; Leaf, 2018; Dupas et al., 2019a; Le
1723 Moal et al., 2019).

1724 One reason for our position that nutrient prevention should
1725 be prioritized over attenuation is simply the immense fertilization
1726 capacity of our global society (Gruber and Galloway, 2008;
1727 Seitzinger et al., 2010). The capacity of ecosystems to assimilate
1728 or remove N and P can easily be overwhelmed by human
1729 nutrient inputs, and recovery from nutrient saturation can take
1730 decades to millennia (Dupas et al., 2018; Goyette et al., 2018;
1731 Haas et al., 2019; Randall et al., 2019). This raises the question
1732 of how can nutrient inputs be decreased while also achieving
1733 the sustainable development goal of eliminating malnutrition?
1734 One solution would be to only use N and P fertilizers to feed
1735 humans (Sutton et al., 2013). While population is projected
1736 to increase through 2050, most of the projected increases in
1737 global nutrient use stems from shifts in diet and per-capita
1738 consumption rather than population growth per se (Seitzinger
1739 et al., 2010; Liu et al., 2012; Sutton et al., 2013; Godfray et al.,
1740 2018). More than half of the global human nutrient and water
1741 footprints are due to livestock (Pelletier and Tyedmers, 2010;
1742 Herrero et al., 2013; Mekonnen and Hoekstra, 2015; Abbott
1743 et al., 2019), even though animal products represent a small
1744 portion of global nutrition and actually have a net negative
1745 effect on human health in many developed countries (Lassaletta
1746 et al., 2014; Godfray et al., 2018; Willett et al., 2019). This
1747 means that decreasing meat and dairy consumption could
1748 substantially reduce nutrient inputs while improving human
1749 health (Sutton et al., 2013; de Vrese et al., 2018; Godfray
1750 et al., 2018; Willett et al., 2019). Additionally, the creation of
1751 biofuels is incredibly nutrient intensive, though only marginally
1752 advantageous energetically and economically (Dominguez-Faus
1753 et al., 2009; Yang et al., 2011). Reducing livestock husbandry
1754 and biofuel cultivation—i.e., limiting fertilizer use to crops
1755 destined for direct human consumption—could decrease the
1756 global nutrient footprint by more than half, while also
1757 alleviating pressure on wildlife habitat and other Earth systems
1758 (Steffen et al., 2015; Springmann et al., 2018; Abbott et al., 2019).

1759 While large-scale changes in diet and energy production
1760 have social and technical challenges of their own (Godfray

1768 et al., 2018; Willett et al., 2019), they could substantially reduce
1769 eutrophication together with expanded control of nutrient
1770 point sources (e.g., wastewater treatment plants), which has
1771 been extremely effective at reducing nutrient export (Musolff
1772 et al., 2015; Abbott et al., 2018b; Le Moal et al., 2019).
1773 Assessing nutrient attenuation capacity at watershed scales with
1774 hydrochemical proxies could also contribute to these efforts by
1775 informing redistribution of essential human activities to more
1776 resistant or resilient parts of the landscape (Thomas et al., 2015;
1777 Abbott et al., 2018a; Dupas et al., 2019b; Refsgaard et al., 2019).

1778 DATA AVAILABILITY STATEMENT

1779 All datasets generated for this study are included in the
1780 article/**Supplementary Material**.

1781 AUTHOR CONTRIBUTIONS

1782 BA and GP conceived the sampling design. RF, BA, SG, TK,
1783 and RD carried out field and laboratory work. RF, BA, and
1784 RD developed the core ideas of the paper with substantial
1785 contributions from all authors.

1786 FUNDING

1787 RF was funded by the Office of Research and Creative Activities
1788 at Brigham Young University (BYU) to promote experiential
1789 learning outside the classroom. BA was supported by the
1790 Department of Plant and Wildlife Sciences and College of
1791 Life Sciences at BYU. The initial sampling and analysis were
1792 supported by supported by the European Union's Seventh
1793 Framework Program for research, technological development
1794 and demonstration under grant agreement no. 607150 (FP7-
1795 PEOPLE-2013-ITN-INTERFACES—Ecohydrologic interfaces as
1796 critical hotspots for transformations of ecosystem exchange
1797 fluxes and biogeochemical cycling).

1798 ACKNOWLEDGMENTS

1799 We thank François Rouault at Agrocampus Ouest for his field
1800 assistance and expertise, and we thank Gabriel Cano at BYU for
1801 his guidance on model selection.
