Abstract

In this article I present a review of InSAR observations of ground deformation at Cordón Caulle volcano, whose 2011-2012 VEI 4-5 eruption is the best scientifically observed and instrumentally recorded rhyolitic eruption to date. I document a complete cycle of pre-eruptive uplift, co-eruptive subsidence and post-eruptive uplift with InSAR data between March 2003 and May 2020 and produced by a complex interplay of magmatic processes. Pre-eruptive data show ~ 0.5 m of ground uplift in three distinct episodes between 2003 and 2011, with uplift rates between ~ 3 and ~ 30 cm/yr. The uplift was likely caused by magma injection resulting in pressurization of the magmatic system at depths of 4-9 km. Data spanning the first 3 days of the eruption show ~ 1.5 m of deflation produced by two distinct sources at 4-6 km depth located 18 km from each other and up to 10 km from the eruptive vent — suggesting hydraulic connectivity of a large magma mush zone. A third source of deformation was recorded during the rest of the eruption at a depth of ~ 5 km, resulting in a total subsidence of ~ 2.5 m. On a much smaller spatial scale (~ 25 km²), InSAR-derived digital elevation models recorded ~ 250 m of uplift in the area of the eruptive vent interpreted as the intrusion of a shallow laccolith during the first 2.5 months of the eruption and time averaged lava discharge rates up to ~ 150 m³/s. The co-eruptive time series of reservoir pressure drop and extruded volume follow exponential trends that can be explained by a model of magma reservoir depressurization and conduit flow. Since the end of the eruption, the surface of the volcano was uplifted ~ 1 m in a sequence of three transient episodes of unrest during 2012 and 2019, with uplift rates between 6 and 45 cm/yr and lasting between 0.5 and 3.2 years. These pulses can be modeled by the same source, a sub-horizontal sill at a depth of ~ 6 km. Viscoelastic relaxation is not significant on these time scales, hence I interpret these uplift signals as being produced by episodic pulses of magma injection in the crystal mush that likely underlies the volcano. The episodic and abrupt changes of the ground deformation suggests a restless trans-lateral magmatic system at depths of 4-9 km and active across multiple spatial and temporal scales. Finally, I also discuss challenges of the InSAR technology that should be addressed to detect ground deformation on short time scales, particularly under the low coherence conditions of Cordón Caulle.

1 Introduction

Volcanic eruptions are one of the most spectacular geological processes observed on Earth. These events are produced by the ascent and extrusion of magma, molten rock composed of melt, crystals, and gases. The occurrence, duration, and style (either explosive or effusive) of the resulting eruption depend on a complex interplay of factors. These include the magma volume, ascent rate, composition, volatile content, and physicochemical transformations that the magma undergoes as it ascends and depressurizes, traveling from its storage area in a shallow reservoir through either a narrow conduit or a sill to the surface (*Wilson et al., 1980; Tait et al., 1989; Jaupart and Tait, 1990; Jaupart, 2000; Edmonds and Wallace, 2017; Tait and Taisne, 2012; Dufek et al., 2012; Gonnermann and Manga, 2012; Gonnermann, 2015*). The complexity of volcanic processes has been recently highlighted by a review article which stated that the first grand challenge in volcano science is to “*forecast the onset, size, duration, and hazard of eruptions by integrating observations with quantitative models of magma dynamics*” (*National Academies of Sciences and Medicine, 2017*). Fortunately, eruptions and/or the emplacement of magma in the upper crust are typically preceded by several signs of unrest including changes in ground deformation (e.g., *Pinel et al., 2014*), temperature (*Reath et al., 2019*), seismicity (e.g., *Chouet and Matoza, 2013*), and degassing (e.g., *Carn et al., 2016*) that can provide insights into their dynamics, and potentially forecast them (*Sparks et al., 2012*). However, there are still basic volcanological questions that remain unanswered. These include: 1. How is magma stored and transported in the crust? 2. What triggers eruptions? 3. What controls the duration and magnitude of eruptions? 4. What unrest signals are evidence of an imminent eruption? (*National Academies of Sciences and Medicine, 2017; Wilson, 2017*). Even in the best monitored volcanoes on Earth, eruption forecasting can be very challenging (*Thelen et al., 2017; Peltier et al., 2018*). Our understanding of the dynamics of these systems is still incomplete because we are inherently limited by the low resolving power of observations made from the Earth’s surface (*Bachmann and Huber, 2016*) rather than in the actual reservoirs where magma is stored (*Lowenstern et al., 2017*).

Ground deformation data is a useful tool for volcano monitoring because the ascent of magma and the resulting eruption are usually coeval with displacement on the Earth’s surface (*Sparks et al., 2012*). Thereby deformation allows us to potentially forecast and better understand volcanic processes. Volcano geodesy has traditionally relied on ground measurements including tiltmeters and continuous GPS but it has been revolutionized by Interferometric Synthetic Aperture Radar (InSAR), providing new insights on a variety of volcanic processes like eruption dynamics (*Dzurisin and Lu, 2007; Pinel et al., 2014; Lu and Dzurisin, 2014; Dumont et al., 2018; Dzurisin et al., 2019*). The key advantage of InSAR is that it is the only geodetic method that can measure ground deformation over large areas ($> 40 \times 40 \text{ km}^2$) with repeat periods of a few days and with small uncertainties ($\sim 5 \text{ cm}$ per interferogram). Com-

76 pilations of satellite observations show a wide diversity of InSAR-derived deformation signals
77 on volcanoes in Latin America (*Reath et al., 2019*) and elsewhere (e.g., *Lu and Dzurisin,*
78 *2014*), but the relation between deformation and eruption is not always clear (*Biggs et al.,*
79 *2014; Biggs and Pritchard, 2017; Delgado et al., 2017; Reath et al., 2019*).

80 In this review article I present a summary of 17 years of InSAR observations at Cordón
81 Caulle volcano (*Figure 1*) in the Southern Volcanic Zone (SVZ) of the Chilean and Argentinian
82 Andes (*Stern, 2004*) and the magmatic processes that can be unravelled with InSAR
83 observations. Although InSAR data have contributed to key observations of volcanic pro-
84 cesses in the SVZ, particularly during the VEI4-5 2008-2009 Chaitén (*Wicks et al., 2011*)
85 and 2015 Calbuco (*Nikkhoo et al., 2016; Delgado et al., 2017*) eruptions and a sequence of
86 unrest at Laguna del Maule volcano (*Feigl et al., 2014; Le Mével et al., 2015; Novoa et al.,*
87 *2019*), in no other volcano in the SVZ than at Cordón Caulle it has shed light about a wide
88 variety of volcanic processes (*Pritchard and Simons, 2004; Fournier et al., 2010; Jay et al.,*
89 *2014; Bignami et al., 2014; Delgado et al., 2016, 2018, 2019; Castro et al., 2016; Wendt et al.,*
90 *2017; Evillades et al., 2017*). These include a sequence of transient pre-eruptive pulses of
91 magma injection, co-eruptive subsidence, lava flow extrusion and shallow laccolith intrusion,
92 lava flow subsidence, and episodic post-eruptive magma injection that can lead to a potential
93 new eruption (*Figure 2*). At the time of writing (July 2020), no other subduction volcano
94 in America except for Okmok in the Aleutians (*Lu and Dzurisin, 2014*) displays the wide
95 variety of signals due to magmatic and superficial processes that can be observed with In-
96 SAR. The discovery of ground deformation at Cordón Caulle has been directly related to
97 improvements in the SAR civilian platforms. Therefore, in this review I rely on multiplat-
98 form InSAR data and relate them to other geological observations (*Castro et al., 2013, 2016;*
99 *Bonadonna et al., 2015*) only when they are relevant for the scope of this study.

100 I start this review with a summary of InSAR and volcano geodesy studies in the Southern
101 Andes, highlighting the value of the method with respect to other geodetic techniques,
102 particularly for the scope of this special issue on **New advances on SAR Interferometry**
103 **in South America**. I then describe a complete cycle of pre-eruptive uplift, co-eruptive
104 subsidence and post-eruptive uplift at Cordón Caulle imaged with InSAR. Then, I describe
105 volcanological aspects where InSAR has made a leap forward in our understanding of rhyolitic
106 dynamics. I finalize with a discussion on the challenges and opportunities for a better use of
107 InSAR in the Southern Andes, including a qualitative comparison of different SAR data sets
108 for the environmental conditions of Cordón Caulle. The time period of this study starts in
109 March 2003 and ends in January 2020. It spans since the beginning of the operation phase
110 of ENVISAT which was the first platform to systematically acquire data in the area to the
111 current COSMO-SkyMED, TerraSAR-X, Sentinel-1, ALOS-2 and RADARSAT-2 acquiring
112 several hundreds of SAR images per year. Therefore, significant changes in the InSAR
113 technology have resulted in a much faster discovery and better understanding of magmatic
114 processes than before.

2 Volcano Geodesy in the Southern Andes

The Southern Volcanic Zone (SVZ) (Figure 1) is one of the most active volcanic segments in the Andean volcanic arc of South America (Stern, 2004) with a time-averaged eruption rate of ~ 0.5 events/year during the 20th century (Dzierma and Wehrmann, 2012). The rate increased to ~ 1.3 events/year between 2008 and 2016 (Llaima January 01 2008, Chaitén May 02 2008-2009, Llaima April 03 2009, Cordón Caulle 04 June 2011, Peteroa 2010-2011, Hudson October 26 2011, Copahue December 2012, Villarrica 03 March 2015, Calbuco April 22 2015, Nevados de Chillan January 2016 - ongoing). These volcanoes have a wide range of eruptive styles that vary from small basaltic Strombolian (VEI 1-2) to large rhyolitic Plinian (VEI 5) eruptions. The SVZ includes Villarrica and Llaima, two of the most active edifices in South America with each having more than 50 historical eruptions since the mid XVI century. Of the 9 SVZ volcanoes that erupted during 2008-2017, Chaitén, Cordón Caulle, Villarrica and Calbuco are scientifically important regardless of their magma composition. The VEI 4-5 2008-2009 Chaitén and 2011-2012 Cordón Caulle eruptions were the first and second rhyolitic eruptions with scientific instrumental observations in real time (Major and Lara 2013; Jay et al. 2014), the latter the first time that the extrusion of a rhyolitic lava flow has been observed in detail (Tuffen et al., 2013). Villarrica is a basaltic/andesitic volcano that hosts one of the seven semi-permanent lava lakes on earth (Lev et al., 2019). Finally, the VEI 4 2015 Calbuco eruption is a rare case of a sub-Plinian andesitic eruption with little to none geodetic and seismic precursory activity (Delgado et al., 2017). The SVZ is thus an excellent place to constrain the mechanisms responsible for magma storage and transport, as well as to investigate how eruptions are triggered and evolve.

InSAR data have been recorded in the SVZ since 1993 (Pritchard and Simons, 2004), but systematic observations with good interferometric coherence have only been available since January 2007 by ALOS-1 data (Fournier et al., 2010). InSAR provided the first geodetic observations in the SVZ volcanoes because to my knowledge classical ground geodesy such as tiltmeters and leveling were never attempted in this region. Several InSAR studies have been carried out in the SVZ including regional surveys (Pritchard and Simons, 2004; Fournier et al., 2010; Pritchard et al., 2013; Delgado et al., 2017; Reath et al., 2019) and detailed studies focused on individual volcanoes. These include from N to S Peteroa (Romero et al., 2020), Laguna del Maule (Feigl et al., 2014; Le Mével et al., 2015, 2016; Novoa et al., 2019; Zhan et al., 2019), Domuyo (Astort et al., 2019; Lundgren et al., 2020), Nevados de Chillán (Pritchard et al., 2013; Reath et al., 2019; Delgado, 2018), Copahue (Velez et al., 2011, 2015; Lundgren et al., 2017; Reath et al., 2019), Lonquimay (Fournier et al., 2010), Llaima (Fournier et al., 2010; Bathke et al., 2011; Remy et al., 2015; Delgado et al., 2017), Villarrica (Delgado et al., 2017; Reath et al., 2019), Cordón Caulle (Jay et al., 2014; Bignami et al., 2014; Delgado et al., 2016, 2018, 2019; Wendt et al., 2017; Evillades et al., 2017), Calbuco (Nikkhoo et al., 2016; Delgado et al., 2017), Chaitén (Fournier et al., 2010; Wicks et al., 2011;

153 *Reath et al., 2019*) and Hudson (*Pritchard and Simons, 2004; Delgado et al., 2014; Reath*
154 *et al., 2019*). These studies show that the SVZ volcanoes have in general shallow magma
155 reservoirs ($z < 10$ km), with injection rates of ~ 0.01 - 0.03 km³/yr. Some of these reservoirs
156 are significantly offset from the center of the volcano (*Delgado et al., 2017*). In some cases
157 deformation preceded eruptions, while in some it did not (*Reath et al., 2019*). The 2008-2009
158 Chaitén, 2011-2012 Cordón Caulle and 2015 Calbuco VEI 4-5 eruptions all were coeval with
159 ground subsidence due to magma extraction from shallow reservoirs.

160 The large number of eruptions and the discovery of deforming volcanoes with InSAR in
161 the past 12 years led to the deployment of continuous GPS and tilt meters for continu-
162 ous monitoring in several volcanoes of the SVZ by OVDAS (Observatorio Volcanológico de
163 los Andes del Sur), part of the Chilean Volcano Monitoring Network operated by SERNA-
164 GEOMIN (Servicio Nacional de Geología y Minería). The first permanent continuous GPS
165 stations in the SVZ were deployed in October 2011 - February 2012 and in December 2017
166 for Cordón Caulle. Nevertheless, the late deployment of these instruments with respect to
167 the eruptions and episodes of unrest implies that only in a few cases they have contributed
168 to a better understanding of volcano dynamics in the SVZ with respect to InSAR (e.g., *Le*
169 *Mével et al., 2015*). Further, no permanent GPS stations existed at the time of the Chaitén,
170 Cordón Caulle and Calbuco eruptions. Stations were deployed after the onset of the Chaitén
171 (*Pina-Gauthier et al., 2013*) and Cordón Caulle eruptions (*Wendt et al., 2017*), and a single
172 tiltmeter recorded the 2015 Calbuco eruption (*Delgado et al., 2017*). However, the few data
173 and the large distance with respect to the volcanoes required to interpret the data jointly
174 with the InSAR observations. Finally, microgravity has only been recorded at Laguna del
175 Maule volcano (*Miller et al., 2017*), with an ongoing continuous microgravity deployment at
176 the summit of Villarrica volcano (Hélène Le Mével, personal communication).

177 **3 Cordón Caulle Geological Background**

178 Cordón Caulle is a long-lived system made up of a graben bounded by two sets of NW-SE
179 trending fissures and the central volcano of a NW-SE volcanic range made up by Cordillera
180 Nevada caldera to the NW and Puyehue volcano to the SE (*Figure 1, Lara et al., 2004,*
181 *2006a,b*). These three volcanoes have chemically distinct evolutions, with Cordón Caulle
182 erupting only rhyolitic and rhyodacitic lavas in the Holocene (*Singer et al., 2008*). The lava
183 flows erupted in 1921-1922 and 1960 were sourced from vents located in the S fissure (*Lara*
184 *et al., 2004; Singer et al., 2008*) and are rhyodacites and rhyolites respectively, with their
185 rare earth element patterns overlapping suggesting a common magma source (*Castro et al.,*
186 *2013*). The VEI 4 1960 eruption occurred 1.5 days after the 1960 M_w 9.5 Valdivia megathrust
187 earthquake suggesting a link between the two (*Barrientos, 1994; Lara et al., 2004*).

188 The 2011-2012 eruption of Cordón Caulle (*Figure 1*) started on June 4, 2011 lasting for ~ 9

189 months until March 2012, and was the first eruption of the volcano since 1960. The eruption
190 was preceded by significant ground uplift between 2007 and 2011 (*Jay et al., 2014*) and by 2
191 months of seismicity above background levels (*Wendt et al., 2017; Delgado et al., 2018*). The
192 eruptive vent was located on the northern scarp that bounds the graben structure (*Figure 1*).
193 The climactic phase of the eruption lasted ~ 27 hours and ejected a ~ 9 - 12 km high eruptive
194 column, with a VEI of 4-5 with a mass flow rate (MFR) of $\sim 10^7$ kg/s, which then decreased
195 to $\sim 10^6$ kg/s (*Bonadonna et al., 2015*). The eruption style shifted from purely explosive
196 to hybrid explosive-effusive on June 15, with the extrusion of ~ 0.6 km³ of a rhyolitic lava
197 flow (*Coppola et al., 2017, Figure 1*) punctuated by mixed ash-gas jets with Vulcanian blasts
198 (*Schipper et al., 2013; Castro et al., 2014*) with MFR $< \sim 10^6$ kg/s, and correlated with
199 an increase in the quasi-harmonic tremor (*Bertin et al., 2015*). The lava time averaged
200 discharge rate (TADR) decreased exponentially from the onset of extrusion until October-
201 November 2011 (*Coppola et al., 2017*), when a second pulse of lava effusion increased both
202 the quasi-harmonic tremor and TADR until the eruption ended in March 2012 (*Bertin et al.,*
203 *2015; Coppola et al., 2017*). A shallow laccolith with a volume of ~ 0.8 km³ was emplaced
204 at depths of 0.2-0.4 km during the first month of the eruption in the transition from purely
205 explosive to hybrid explosive-effusive activity (*Castro et al., 2016; Delgado et al., 2019*). The
206 total erupted volume is ~ 1.22 km³ for the tephra erupted between June 4-7, 2011 (*Pistolesi*
207 *et al., 2015*) and ~ 1.2 km³ bulk (*Castro et al., 2016*) to 1.45 km³ DRE (*Delgado et al.,*
208 *2019*) for the lava flow and the shallow laccolith. Field observations in early January 2012
209 showed that the lava extrusion was coeval to a weak eruptive column, gas and ash jetting
210 punctuated by short Vulcanian blasts (*Schipper et al., 2013*). The erupted magma has a
211 rhyolitic composition (explosive phase pumice 69.5% SiO₂, lava 71-72% SiO₂) that overlaps
212 with the composition and rare earth elements of the 1960 and 1921-1922 eruptions, and was
213 stored at depths between 2.5 and 6 km (*Castro et al., 2013; Jay et al., 2014; Wendt et al.,*
214 *2017*). The explosive phase magma was nearly aphyric resulting in a highly mobile rhyolite
215 with fast ascent rates (*Castro et al., 2013*).

216 4 InSAR methods

217 In this review I have included observations from almost every SAR mission available since
218 2003, which include ENVISAT, ALOS-1, TerraSAR-X/TanDEM-X (TSX/TDX), COSMO-
219 SkyMED (CSK), RADARSAT-2 (RS2), UAVSAR, Sentinel-1 (S1) and ALOS-2 (*Table 1*).
220 Data from ERS-1/2 are only briefly described due to its low quality (*Pritchard and Simons,*
221 *2004*). SAR data from the legacy JERS and RADARSAT-1 and from the newer SAOCOM-1
222 and PAZ missions are not available.

223 The first InSAR studies at Cordón Caulle (*Pritchard and Simons, 2004; Jay et al., 2014*)
224 used individual interferograms processed with a standard range-Doppler processing chain

225 implemented in the legacy JPL ROI-PAC software (*Rosen et al., 2004*). New algorithms and
226 processing tools like SAR focusing with a motion compensated orbit (*Zebker et al. 2010*), ge-
227 ometric coregistration (*Sansosti et al., 2006*) and zero-Doppler processing (*Eineder, 2003*) for
228 individual interferograms and time series have been implemented in the JPL ISCE (*Rosen*
229 *et al., 2012*) and ISTERre/IPGP NSBAS (*Doin et al., 2011; Grandin, 2015*) software. All
230 the interferograms and time series presented in this study (*Figure 3 - Figure 6*) were pro-
231 cessed with the ISCE software except two co-eruptive ENVISAT interferograms which were
232 processed with the ROI-PAC software (*Figure 4a-b, Jay et al., 2014*) and the Sentinel-1
233 descending time series (*Figure 5*) that was processed with the NSBAS software. Data pro-
234 cessing is described in detail in the supplementary information (SI) and elsewhere (*Delgado*
235 *et al., 2016, 2017*). Due to the improvement of the InSAR workflows and a better data
236 availability, I have used these new tools to reprocess interferograms from the now legacy
237 ENVISAT and ALOS-1 missions presented in previous studies (*Jay et al., 2014; Evillades*
238 *et al., 2017; Wendt et al., 2017*). These results include new ALOS-1 time series and a source
239 model for the first episode of ENVISAT-detected uplift between 2003 and 2007, which extend
240 the sequence of pre-eruptive uplift from February 2007 (*Jay et al., 2014*) to February 2003.
241 Further, I have also expanded CSK, RS2 and S1 time series from May 2018 (*Delgado et al.,*
242 *2018*) to May 2020.

243 **5 InSAR observations**

244 In this section I describe all the deformation signals observed between 2003 and 2020 at
245 Cordón Caulle.

246 **5.1 Pre-eruptive ground deformation**

247 **5.1.1 1993-1996**

248 *Pritchard and Simons, 2004* presented a single ERS-1/2 interferogram that recorded 8 cm of
249 subsidence at the Cordón Caulle graben during 1996-1999. The limited temporal resolution
250 of this interferogram and the lack of other independent data results in a large degree of uncer-
251 tainty in the interpretation of this deformation signal, which has been attributed to changes
252 in the hydrothermal system of the volcano (Matthew Pritchard, personal communication).
253 Therefore this data set is not considered further in this study.

254 5.1.2 2003-2007

255 The first unambiguous observations of ground uplift were recorded by ENVISAT IM2 as-
256 cending and descending interferograms (*Fournier et al., 2010*) and span 2003 to 2007, with
257 a maximum line-of-sight uplift rate of $\sim 3\text{-}4$ cm/yr observed at the Cordón Caulle graben
258 (*Figure 3a-b* and *Figure S1*). These interferograms can be modeled by the opening of a sub
259 horizontal sill at a depth of 5.2 km with a total volume change of 0.013 km^3 during 2003-2007
260 (*Supplementary Material*).

261 5.1.3 2007-2011

262 A second pulse of uplift was detected by ALOS-1 ascending interferograms which recorded
263 ~ 30 cm during January 2007 and February 2008 (*Figure 3c*). The deformation signal is
264 located on both Cordón Caulle and Cordillera Nevada caldera and can be modeled by two
265 spherical sources at depths between 2.8 and 4.1 km, with a total volume change of 0.023
266 km^3 (*Fournier et al., 2010; Jay et al., 2014*). The poor temporal sampling of the data does
267 not allow to properly assess the temporal evolution of uplift

268 A third pulse of uplift occurred during mid 2008 to early 2009, with a maximum uplift
269 of ~ 15 cm recorded by ALOS-1 ascending data. The deformation signal was observed in
270 the W flank of Cordón Caulle and is different in location to that of the 2007-2008 episode
271 (*Figure 3*). Because the line-of-sight (LOS) is the same than for the the 2007-2008 episode of
272 uplift, the shift in location is produced by a different source compared to that of 2007-2008.
273 Different deformation sources (small sphere, prolate spheroid, sill) can model the data, with
274 depths between 5 and 9 km, although none can properly fit both ascending stacks and a
275 single descending interferogram (*Figure 3f*). The source volume change during 2008-2009
276 is 0.03 km^3 for the spherical source (*Jay et al., 2014*). *Jay et al., 2014* showed that uplift
277 paused between 2009 and 2010, but the ALOS-1 time series shows that uplift continued from
278 2010 to 2011 (*Figure 3*). Therefore I consider that the episode lasted between May 2008 and
279 January 2011.

280 *Jay et al., 2014* observed a small uplift signal located within Cordillera Nevada caldera
281 near the Trahuilco geyser (*Sepulveda et al., 2004*) that occurred between February 13 2010
282 and March 31 2010 (*Figure 3d*). This deformation signal was modeled with a very shallow
283 spherical source at a depth of 1.7 km with a volume change of 0.0014 km^3 .

284 A fourth pulse of uplift with an amplitude of 5 cm was recorded by ENVISAT IM6 data
285 during March-May 2012. The data can be modeled with a sill at a depth of 4 km with a total
286 volume change of 0.003 km^3 (*Jay et al., 2014*). However *Euillades et al., 2017* speculated that
287 the signal observed in this interferogram could be an atmospheric artifact, but pair-wise logic
288 could not be applied to discriminate between these two scenarios. Due to this discrepancy,

289 this signal is not considered further.

290 Therefore, InSAR data suggests at least three pulses of pre-eruptive uplift at depths between
291 3 and 9 km. The simplest and most likely mechanism to explain these signals is magma
292 injection in a shallow crystal mush underlying the volcano because the deformation sources
293 are much deeper than the inferred depth of the shallow hydrothermal system (*Sepulveda*
294 *et al.*, 2005, 2007; *Jay et al.*, 2014). The spatial shift in location of the deformation signals
295 results from magma injection in different parts of the plumbing system of Cordón Caulle
296 and will be discussed with detail later in the manuscript. The only exception is the localized
297 deformation in the Trahuilco Geyser in early 2010, which *Jay et al.*, 2014 interpreted to
298 be of hydrothermal origin in response to the dynamic triggering of the 2010 M_w 8.8 Maule
299 earthquake.

300 5.2 Co-eruptive ground deformation

301 The co-eruptive ground deformation signals are different compared with those of the sequence
302 of pre-eruptive uplift. The eruption started 2 months after the end of the ALOS-1 mission
303 and during the ENVISAT extension mission. The latter was the only satellite that recorded
304 data throughout the complete eruption and was the core data analyzed by all the studies
305 that have studied the eruption with InSAR (*Jay et al.*, 2014; *Bignami et al.*, 2014; *Wendt*
306 *et al.*, 2017; *Euillades et al.*, 2017; *Delgado et al.*, 2019), with five additional TSX and RS2
307 interferograms processed by *Delgado et al.*, 2019.

308 A 30-day interferogram that spans the first three days of the eruption (June 04-07 2011)
309 shows 1.3 and 0.3 m of LOS subsidence at Cordillera Nevada caldera and Puyehue volcano
310 respectively (*Figure 4a*, *Jay et al.*, 2014; *Bignami et al.*, 2014; *Wendt et al.*, 2017). The
311 subsidence was produced by deflating sources located at depths of 3.8 and 6.1 km with a
312 total volume change of $\sim 0.11 \text{ km}^3$ respectively. The deformation sources are offset 10-15
313 km from the eruptive vent which implies a mechanism of lateral magma transport from
314 these lateral sources to the eruptive vent. Interferograms that span the rest of the eruption
315 have no coherence on top of the volcano until the eruption waned and coherence increased
316 during the 2011-2012 austral summer. Nevertheless, all of these data sets record several
317 tens of centimeters of subsidence due to lava effusion (*Figure 4b-c*). The post June 7 2011
318 deformation signal can be modeled by a finite-sized prolate spheroid calculated with the finite
319 element method based on the inversion for an analytic model (*Delgado et al.*, 2019), providing
320 better model fits than previous attempts with a single Mogi source (*Jay et al.*, 2014; *Wendt*
321 *et al.*, 2017). The spheroid depth is ~ 5.2 km below the volcano, centered on the graben and
322 oriented in the direction of the volcanic chain. The spheroid semi-major and semi-minor
323 axes are 10 and 2.5 km respectively (*Figure 4*, *Figure 7*). *Delgado et al.*, 2019 inverted 20
324 coherent interferograms with the spheroid source fixed to retrieve a time series of pressure

325 change that follows an exponential trend (shown in [Figure 4](#) for the effusive phase only). The
326 best-fit spheroid and the time series of pressure change predict a pressure drop of ~ 20 - 50
327 MPa, a reservoir volume change of 0.5 km^3 , and ~ 2.2 - 2.7 m of LOS subsidence on top of the
328 volcano ([Figure 2](#)). The data also suggests a slight change in the deformation source during
329 the second half of the eruption, in agreement with a second pulse of lava effusion ([Bertin](#)
330 *et al.*, 2015; [Coppola et al., 2017\), but the change was minor and therefore not described
331 here further. These three deflating sources \(two during June 04-07 2011 and one during the
332 rest of the eruption\) are consistent with three bodies of magma tapped during the first week
333 of the eruption \(\[Alloway et al., 2015\\). In general the depths of the spherical and prolate
334 spheroidal sources of 4-6 km are in agreement with depths inferred from geobarometry \\(\\[Jay\\]\\(#\\)
335 *et al.*, 2014\\) and experimental decompression of the mineral phases observed in the erupted
336 tephra \\(\\[Castro et al., 2013\\\).\\]\\(#\\)\]\(#\)](#)

337 5.2.1 Lava flow effusion and laccolith intrusion

338 TanDEM-X CoSSC (Coregistered Slant range Single look Complex) data were acquired
339 before and several times during the effusive phase of the eruption. These data were used
340 to calculate six high-resolution DEMs that were subtracted to produce differential DEMs
341 (dDEM) that allow to calculate both time-averaged discharge rates (TADR) and time series
342 of extruded volume. The dDEM data show a maximum thickness of ~ 150 m for the lava
343 flow and an area of topographic increase up to ~ 250 m immediately east of the lava flow and
344 the eruptive vent ([Figure 4e-f](#)). This area of uplift was interpreted and modeled by [Castro](#)
345 *et al.*, 2016 to be produced by the intrusion of a laccolith at very shallow depths of ~ 0.2 - 0.4
346 km below the surface. The time series of lava flow and laccolith intrusion volume shows
347 an exponential trend with a total volume of $\sim 1.45 \text{ km}^3$ DRE during the whole eruption
348 ([Figure 2](#)) and $\sim 1.2 \text{ km}^3$ DRE during the effusive phase of the eruption ([Figure 4](#), [Delgado](#)
349 *et al.*, 2019).

350 The temporal resolution of the TDX dDEM data (~ 1 data point every 2 months) does not
351 allow to pinpoint when did the laccolith intruded with respect to the explosive to effusive
352 transition. Single Look Complex (SLC) amplitude images from ENVISAT and TerraSAR-X
353 data were also used to track the growth of the laccolith ([Castro et al., 2016; \[Delgado et al.,
354 2019\\). Both studies conclude that the laccolith was emplaced during both the explosive and
355 effusive phases of the eruption, starting probably during the first 4 days of the eruption and
356 one week before the lava flow effusion. Pixel tracking calculated on these amplitudes images
357 show range and azimuth displacements that exceed \\$\sim 20\\$ m due to laccolith post-emplacment
358 dynamics \\(\\[Figure 4\\]\\(#\\)\\). The displacement is large enough that it can be observed directly in
359 the coregistered amplitude images \\(not shown\\).\]\(#\)](#)

360 5.2.2 Physicochemical model of the effusive phase of the eruption

361 The 2011-2012 eruption is one of the few effusive eruptions to date where both time series
 362 of ground deformation and topographic change were acquired nearly simultaneously, and
 363 that showed quasi-exponential trends, like those observed in other eruptions (*Anderson and*
 364 *Segall, 2011*). This makes the 2011-2012 eruption one of the few of this kind where a time-
 365 dependent physicochemical model can be attempted, like at Mt St Helens (*Anderson and*
 366 *Segall, 2013*).

367 The physicochemical model developed by *Delgado et al., 2019* is adapted from *Anderson and*
 368 *Segall, 2011, 2013* and simulates the pressure drop in a magma reservoir ($\Delta P(t)$) and the lava
 369 extrusion ($\Delta V(t)$) driven by this pressure drop. Here magma ascends to the surface through a
 370 conduit from a depressurized horizontal prolate spheroid reservoir that contains isothermal
 371 magma made up of melt, crystals, and exsolved and dissolved volatiles in a linear elastic
 372 half-space under a lithostatic load. As magma outflows from the reservoir, the flow rate is
 373 controlled by the conduit radius, reservoir pressure, and magma viscosity, which is a function
 374 of the dissolved H₂O and the crystal volume fraction. During the eruption, magma piles up
 375 on top of the eruptive vent, increasing the lithostatic load on the reservoir, and reducing the
 376 pressure gradient that drives the conduit flow. Since the data have no sensitivity to conduit
 377 processes, magma properties were assumed constant in the conduit and allowed to vary only
 378 in the reservoir. The model can be solved with different levels of complexities for constant
 379 magma properties (hereafter exponential model), constant magma properties but with a
 380 time-dependent surface load due to magma extrusion (hereafter lava load model) and time-
 381 dependent magma properties in the reservoir and with a time-dependent surface surface load
 382 (hereafter physicochemical model). The model parameters are the magma compressibility
 383 (β_m), conduit conductivity (ratio of the fourth power of conduit radius and magma viscosity)
 384 and pressure drop (p_{ch}) for the exponential and lava load models, and the initial overpressure,
 385 conduit radius, total CO₂ and H₂O in the magma for the physicochemical model. [Equation 1](#)
 386 - [Equation 2](#) show the analytic model (equations 1-4 in *Delgado et al., 2019* and A11-A12 in
 387 *Anderson and Segall, 2011*),

$$\Delta P(t) = -p_{ch}(1 - e^{-t/\tau}) \quad (1)$$

$$\Delta V(t) = V_0(\beta_m + \beta_{ch})p_{ch}(1 - e^{-t/\tau}) \quad (2)$$

389 with V_0 and β_{ch} the reservoir volume and compressibility and τ a time constant function of
 390 the plumbing system geometry. These models predict exponential-like trends for the reservoir
 391 pressure change and the extruded volume, like those observed in the data ([Figure 4](#)).

392 Despite the complexities of the eruption, the low coherence and the poor temporal temporal
 393 resolution of the InSAR data, *Delgado et al., 2019* found that the magma compressibility of

394 the lava flow and intruded laccolith during the effusive phase is $\sim 1 \times 10^{-10} \text{ Pa}^{-1}$. This value
395 is half that of the calculated compressibility for the erupted tephra of $\sim 2 \times 10^{-10} \text{ Pa}^{-1}$ (*Jay*
396 *et al.*, 2014). This is consistent with rhyolitic magma that was degassed with respect to its
397 equilibrium condition at its storage depth of ~ 5 km based on H_2O and CO_2 solubility models
398 (*Delgado et al.*, 2019). The models also predict remarkably well the temporal evolution of
399 the effusive phase, which follows an exponential trend for both the source pressure drop and
400 extruded volume (Figure 4).

401 5.3 Post-eruptive inflation

402 A significant technological change occurred during the end of the eruption. The end of the
403 ENVISAT extension mission coincided with the onset of CSK acquisitions which resulted
404 in an increase in the data temporal resolution by more than one order of magnitude. This
405 resulted in the application of dense InSAR time series for the first time in the volcano with
406 CSK and RS2 stripmap data (*Delgado et al.*, 2016; *Ewillades et al.*, 2017).

407 Deformation following the eruption started almost immediately, with uplift at an extremely
408 fast rate up to 45 cm/yr during March 2012 - January 2013 – the fastest ever detected
409 with satellite geodesy (GPS, InSAR) at a rhyolitic volcano. The uplift rate decreased in
410 March 2013 to ~ 17 cm/yr until May 2015 when deformation abruptly ended. The uplift
411 can be modeled by a pressurized subhorizontal distributed opening sill at a depth of 6.2
412 km with a volume change of 0.125 km^3 (*Delgado et al.*, 2016, uniform opening sill shown in
413 Figure 5). The time series of uplift during 2012-2015 follows an exponential trend which was
414 interpreted by *Delgado et al.*, 2016 to be evidence of magma injection (e.g., *Lengline et al.*,
415 2008; *Le Mével et al.*, 2016), although at the time other deformation mechanisms could not
416 be ruled out. *Delgado et al.*, 2018 tested whether the exponential trend could result due to
417 viscoelastic relaxation following a transient pressure increase in the magma reservoir. They
418 concluded that a model of a pressurized spheroid surrounded by a Maxwell viscoelastic shell
419 with a viscosity of $2 \times 10^{17} \text{ Pa s}$ and a 1 km radius and with a transient pressure function of
420 the form $P = P_f(1 - e^{-t/\tau})$ with $\tau=0.4$ years, $P_f=10$ MPa could fit the data. However, the
421 fit was worst than the magma injection model in an elastic medium, ruling out viscoelastic
422 effects.

423 After one year with no deformation, uplift resumed in July 2016 until February 2017 (*Eu-*
424 *illades et al.*, 2017; *Delgado et al.*, 2018). This episode of uplift marks the first time that a
425 complete multiparametric set of X, C and L band observations from ascending and descend-
426 ing CSK stripmap, S1 TOPS, RS2 Wide Ultra Fine and Wide Fine stripmap and ALOS-2
427 ScanSAR and stripmap data image the same episode of ground deformation at the volcano.
428 The uplift event reached ~ 12 cm in 6 months – equivalent to an uplift rate of ~ 24 cm/yr,
429 and ended abruptly in February 2017 as it did during May 2015. The spatial footprint of

430 the deformation signal is very similar to that of the 2012-2015 episode of uplift. *Delgado*
431 *et al.*, 2018 tested whether the uplift was due to a different source and concluded that it
432 is the same deformation source active during 2012-2015, but with a much smaller volume
433 change of $\sim 0.022 \text{ km}^3$. This yields a total source volume change of 0.147 km^3 during March
434 2012 - February 2017. The lack of interferometric coherence during the winter with C and
435 X-band data and the poor temporal sampling of ALOS-2 L-band data did not allow to assess
436 whether the time series of the 2016-2017 episode of uplift follows an exponential or a double
437 exponential trend as observed elsewhere (*Le Mével et al.*, 2016).

438 *Delgado et al.*, 2018 showed potential evidence for a third pulse of uplift during May 2017
439 - May 2018, but the limited amount of data did not allow to confirm this. New GPS and
440 InSAR observations from CSK, RS2 and S1 (*Figure 5*) show that deformation continued
441 beyond May 2018 during a third episode between May 2017 - May 2019, with a rate of $\sim 5\text{-}6$
442 cm/yr depending on the data set and resulting in a total of 1 m of post-eruptive uplift.
443 As during 2016-2017, the deformation signal during 2017-2019 is very similar to that of
444 2012-2015 suggesting the same deformation source (*Figure 5*).

445 5.3.1 Lava flow and laccolith post-emplacement ground deformation

446 *Delgado et al.*, 2016 presented small baseline RS2 and CSK interferograms spanning two
447 weeks during 2013 and 2014 that recorded $\sim 5\text{-}6$ cm of LOS subsidence in the lava flow,
448 resulting in rates of $\sim 1.2\text{-}1.4$ m/yr. However, the lack of a high resolution DEM at the
449 time of that study did not allow to better track the flow subsidence, reducing the analysis
450 to individual interferograms. A small-baseline stack of RS2 Wide Ultra Fine interferograms
451 that spans February to May 2016 plus two ALOS-2 SM3 interferograms during 2015-2016
452 show a complex pattern of lava flow subsidence with rates up to 0.5 m/yr in some areas of the
453 flow. Other areas of the flow show either uplift or eastward movement towards the satellite.
454 These signals cannot be attributed to a simple mechanism of homogeneous lava flow cooling
455 and subsidence (e.g., *Ebmeier et al.*, 2012) and imply that sections of the flow were mobile,
456 probably flowing laterally four years after the end of the eruption. The extreme thickness of
457 the lava flow suggest that subsidence produced by cooling can last for several decades (e.g.,
458 *Chaussard*, 2016). The RS2 stack shows subsidence in the E part of the laccolith, although
459 analysis of 2016 TanDEM-X bistatic interferograms shows that the phase in the laccolith is
460 proportional to the perpendicular baseline, suggesting a DEM error in that area (*Figure 6*,
461 SI).

6 Discussion

Here I discuss some interesting observations and lessons learned from the Cordón Caulle InSAR data and models. These include mainly the long term evolution of the plumbing system of the volcano, the triggering mechanism and the temporal evolution of the 2011-2012 eruption.

6.1 Deformation sources

Source modeling approaches for Cordón Caulle have ranged from the use of simple spherical models (*Jay et al., 2014*) to viscoelastic finite element models (*Delgado et al., 2018*) and physicochemical models that couple the reservoir pressure drop, conduit flow and magma physicochemical properties (*Delgado et al., 2019*). Despite their simplicity, in general analytic and numerical source models explain the InSAR ascending and descending data well. However, *Jay et al., 2014* could not fit the ascending and descending ALOS-1 data for the 2008-2011 uplift pulse with an analytic model, which suggests that a more complex source geometry is required to model that specific pulse of pre-eruptive uplift.

In general deformation sources are scattered along the extent of the volcanic chain, but clustered near Cordón Caulle (*Figure 7*). The similarity of the deformation sources during 2003-2007, 2007-2008, 2011-2012 during the effusive phase, and 2012-2017 suggest a common zone of magma storage and effusion, which could occur as a neutral buoyancy level at depths of 4-6 km (*Figure 7*). This is in agreement with numerical models that show that magma is preferably stored at those depths (*Huber et al., 2019*). Further, this deformation zone has been episodically active before and after the eruption with slight changes in the source geometry. For example, the model for 2012-2017 cannot fit well the 2007-2008 data (not shown). This source stability in location and time and episodic unrest is similar to other basaltic reservoirs like Okmok (*Lu et al., 2010; Lu and Dzurisin, 2010, 2014*) and Kilauea (*Poland et al., 2014*). In general source spatial migration and stability are not well understood but could be due just to discrete pulses of magma injection occurring across the volcano (e.g., *Dzurisin et al., 2012*). The reason why the 2012-2019 sill source is more stable in location compared with the pre-eruptive sources is unknown. All these observations suggest a large shallow plumbing system (*Jay et al., 2014; Delgado et al., 2016*) made up of either one large crystal mush or several individual reservoirs under cold storage conditions (*Cooper and Kent, 2014*) into which magma is episodically stored and injected. These observations also suggest that the plumbing system of Cordillera Nevada and Puyehue are connected to that of Cordón Caulle, despite the three volcanoes having evolved independently (*Singer et al., 2008*). To what extent the magmas of the three volcanoes interact mechanically, chemically or thermally with each other is currently unknown.

497 The InSAR data indicates that pressure sources instead of dikes can model the data during
498 the onset of the eruption. This hypothesis was explored by *Wendt et al., 2017* and the
499 transition between the explosive and effusive stages of the eruption is better explained with a
500 dike opening model than pressure sources (*Castro et al., 2013*). *Wendt et al., 2017* calculated
501 models of a dike and a sphere for the interferogram that spans the first three days of the
502 eruption (*Figure 4a*), but the model fit was significantly worse than a two sphere model.
503 During the rest of the eruption the prolate spheroid models of *Delgado et al., 2019* can fit the
504 data very well with no need to invoke a dike. Although the dike intrusion is a very plausible
505 idea, the extent of phase decorrelation observed during the onset of the eruption implies
506 that the existing InSAR cannot unambiguously address this point. Very high resolution
507 pixel tracking on TSX stripmap data have the potential to unravel the role of co-eruptive
508 diking.

509 Despite the good fit of the models to the InSAR data, these models are oversimplifications of
510 magmatic systems. Magma reservoirs are crystal mushes (*Bachmann and Bergantz, 2008*)
511 which are better understood in terms of poroelastic mechanisms, but at the day of now these
512 models are novel (e.g., *Liao et al., 2018*) and have not been used to model ground deformation
513 data. Further, these models have a lot of parameters that trade-off with each other and
514 that are not straightforward to constrain with geodetic data. Future studies should consider
515 reservoirs with more arbitrary geometries like the compound dislocation model *Nikkhoo et al.,*
516 *2016*, spheroids of finite-sized dimensions (*Le Mével et al., 2016; Delgado et al., 2019*) and
517 poroelastic models (e.g., *Liao et al., 2018*). Also, the similar location and shape of the
518 deformation sources (*Figure 7, Euillades et al., 2017*) suggests that future studies may also
519 attempt a model that explains jointly the pre-eruptive, co-eruptive and post-eruptive ground
520 deformation data with a common source (e.g., *Lu and Dzurisin, 2010*).

521 **6.2 Eruption triggers**

522 Forecasting eruptions is one of the key questions in volcano science (*Sparks et al., 2012*) and
523 the InSAR observations at Cordón Caulle make this a promising case from which we can
524 draw insights that may improve forecasting of other eruptions. Any triggering mechanism for
525 the 2011-2012 eruption must account for the following facts: a) the eruption was preceded by
526 a transient sequence of at least three pulses of pre-eruptive uplift lasting between 6 months
527 and 4 years or more. (*Figure 2, Figure 3*), b) deformation sources that are scattered along
528 the volcanic chain (*Figure 1*), c) rhyolites are stored as crystal mushes under cold storage
529 conditions and are thermomechanically remobilized by magma injection that enhances melt
530 percolation towards the liquid-rich cap on top of the mush (*Huber et al., 2010, 2011*), and
531 d) ground uplift of very low magnitude to none (*Figure 3*) and an increase in the seismicity
532 between February and April 2011 (*Wendt et al., 2017*). Despite the variety of processes
533 that can be observed and modeled in crystal mushes (*Bachmann and Bergantz, 2006; Huber*

534 *et al.*, 2012; *Papale et al.*, 2017; *Morgado et al.*, 2019), including segregation and merging of
 535 melt-rich layers within a transcrustal mush (*Sparks and Cashman* 2017), at the day of now
 536 all models of ground deformation in volcanoes fall under either of two generic categories:
 537 magmatic or hydrothermal processes. The former includes basalt injection that pressurizes
 538 the plumbing system, magma mixing, thermal heating without mixing and volatile exsolution
 539 among others. For example, it is possible that basalt was injected below Cordón Caulle and
 540 did not mix with the crystal mush, only providing the heat to melt a fraction of the mush
 541 (e.g., *Morgado et al.*, 2019). Nevertheless, the vast majority of the InSAR studies argue
 542 for injection of molten basalt that pressurizes the reservoir walls without further detail.
 543 Since eruptions are triggered by magma injection on time scales shorter than a decade (e.g.,
 544 *Degruyter and Huber*, 2014; *Townsend and Huber*, 2020), in the following I will only consider
 545 the reservoir pressurization and rupture produced by magma injection.

546 A general rupture criteria (*Tait et al.*, 1989; *Pinel and Jaupart*, 2003; *Albino et al.*, 2010)
 547 shows that a dike can propagate from the chamber to the Earth's surface once the deviatoric
 548 component of the minimum compressive stress in the reservoir walls is greater or equal than
 549 the tensile strength of the rock. This means that the magma overpressure is twice the tensile
 550 strength of the rock for a spherical reservoir in an infinite medium (*Tait et al.*, 1989; *Albino*
 551 *et al.*, 2010). An extension of the previous criteria that considers both magma overpressure
 552 and buoyancy for pressurized cavities in an elastic medium is (*Sigmundsson et al.*, 2020)

$$\Delta\rho gh + \Delta P_{magma} \geq \sigma_{failure} + \sigma_{external} \quad (3)$$

553 with the terms from left to right the buoyancy force due to a magma body of thickness h ,
 554 and density contrast $\Delta\rho$ under gravity acceleration g , the magma overpressure ΔP_{magma} ,
 555 $\sigma_{failure}$ the failure limit and $\sigma_{external}$ stress due to other processes (surface loading, flank
 556 instability, transient changes in tectonics stresses, etc). In the absence of external triggers
 557 ($\sigma_{failure} = 0$), an eruption can be triggered by an increase in the magma pressure due to
 558 compressible or incompressible magma injection (ΔP_{magma}), an increase in the thickness of
 559 a buoyant magma body or an increase in the density of the buoyant magma body due to
 560 magma phase transitions in the reservoir, or all of the previous.

561 The 2003 to 2011 deformation sources are at depths of 4 to 9 km, which suggests that episodic
 562 magma injection with a time-variable rate in a large elongated reservoir at a level of neutral
 563 buoyancy is potentially responsible for triggering the eruption. Under the assumption that
 564 the deformation is due to magma injection, the volume change of 0.013 km³ during 2003-
 565 2007 plus the 0.05 km³ during 2007 and early 2011 results in the intrusion ~ 0.063 km³
 566 of incompressible magma. This volume is one order of magnitude lower than the volume
 567 of erupted magma and the co-eruptive source volume change, even accounting for magma
 568 compressibility. The 2003-2007 source volume change is much smaller than the source volume

569 changes during 2007-2011 (*Jay et al., 2014*) therefore their role on potentially triggering the
570 eruption are very minor. The previous argument suggests that if the eruption was triggered
571 by magma injection until the reservoir walls ruptured when the hoop stress reached the tensile
572 strength of the rock, a significant amount of magma must have been intruded before 2003
573 (*Jay et al., 2014*). Unfortunately the volume of this potential magma is unconstrained due
574 to the lack of geodetic data before 1996. Therefore, other mechanism like volatile exsolution
575 (*Tait et al., 1989*) since the previous eruption in 1960 eruption cannot be ruled out. It is
576 also possible that reservoir was brought closer to failure due to magma buoyancy without
577 significant reservoir pressurization that can be detected geodetically (e.g., *Sigmundsson et al.,*
578 *2020*). An alternative mechanism is that magma injection in different parts of the plumbing
579 system of the volcano increased the failure pressure by lateral stress transfer (*Albino and*
580 *Sigmundsson, 2014*). In this mechanism magma injection in a specific section of the plumbing
581 system can increase the failure pressure in other regions below the volcano, without the need
582 for mass injection in the reservoir from which magma will eventually erupt. This mechanism
583 is conceptually equivalent to earthquake triggering by an increase in the static Coulomb
584 stress. The normal stress σ_{rr} in a spherical source embedded in a full space is given by

$$\sigma_{rr} = -\frac{\Delta V G}{2\pi r^3} \quad (4)$$

585 with ΔV the source volume change, G the shear modulus and r the distance (equations 7.7
586 and 7.13 in *Segall, 2010*). The negative sign indicates compression, so a positive volume
587 change produces compression. A volume change of 0.03 km³ in the 2008-2011 source with
588 $G=20-2.1$ GPa (*Delgado et al., 2019; Heap et al., 2020*) can increase the radial stress to 0.06
589 - 2 MPa over distances of 5-7 km, similar to the distance between the 2007-2008 and the
590 early June 2011 deformation sources (*Figure 8*). If either of these reservoirs were in a critical
591 state, these stresses due to magma injection can influence the reservoirs and potentially bring
592 them closer to failure (e.g., *Albino and Sigmundsson, 2014; Biggs et al., 2016*).

593 In summary the InSAR observations allow for multiple mechanisms to explain the eruption
594 triggering. It is also likely that several of these triggering mechanism were coeval and that
595 InSAR just recorded a very low resolution image of these processes (e.g., *Bachmann and*
596 *Huber, 2016; Lowenstern et al., 2017*). Further, the time span covered by the pre-eruptive
597 InSAR observations of ground uplift is only 8 years and it is so short with respect to the
598 previous eruption in 1960 and the time scales of magmatic processes so it is very difficult to
599 disentangle the relevant contribution of these individual processes. Thereby, the complete
600 lack of ground instrumental data before 2010 when seismic monitoring started and the total
601 lack of other observations before 1996 do not allow to unambiguously unravel the triggering
602 mechanism. Due to the large deformation in the past two decades, pixel tracking from
603 either historical satellite or airborne imagery could provide insights on these processes (e.g.,
604 *Derrien et al., 2015*).

6.3 Eruption temporal evolution

Despite the complexity of the eruption with two pulses of lava effusion (Coppola et al., 2017), the intrusion of a shallow laccolith (Figure 4), and three sources of ground deformation (Figure 7), both the erupted volume and pressure change time series derived from InSAR can be explained reasonably well with a simple model. The model is made of a finite-sized spheroid that deflates in response to lava effusion through a conduit, with both the effusion and the deflation following exponential trends (Equation 1-Equation 2). It is true that deviations from exponential trends (e.g., Kubanek et al., 2017) require more complex models including magma permeability (e.g., Wong and Segall, 2019) or a widening dike/conduit (e.g., Castruccio et al., 2017), but the simple trends observed in the data during the effusive phase do not require such level of complexity. The key finding of the physicochemical models is that the magma compressibility during the effusive phase is significantly lower compared with the compressibility inferred for the magma erupted during the explosive phase. This is a consequence of a partially degassed rhyolite with respect to the predicted dissolved H₂O and CO₂ for a storage depth of ~5 km (Delgado et al., 2019). On the other hand, a relevant question is why did the deflating sources shift from Cordillera Nevada caldera and Puyehue volcano to the Cordon Caulle graben during the first month of the eruption? (Figure 4a-b). Since magma flow is proportional to the pressure gradient, the first two reservoirs had less magma capable of flowing than the third one or their hydraulic conductivity decreased very rapidly compared with that of the source below Cordon Caulle. This is a topic that requires further studies.

6.4 Mechanisms of unrest during pre and post-eruptive uplift

The similarities in the ground deformation during the transient uplift in 2003-2007, 2007-2008 and 2012-2019 and their chronology with respect to the eruption suggest that the same processes are responsible for observed signals, which for simplicity I related to magma injection. Since the 2012-2015 uplift started immediately after the end of the eruption, this episode of unrest can be easily explained as a pulse of magma injection. This episode was triggered by the 20-50 MPa co-eruptive pressure drop (Delgado et al., 2019), allowing magma to flow from a deep mantle source to the shallow sill source (e.g., Lengline et al., 2008; Delgado et al., 2016). The prediction of this mechanism is a decreasing exponential trend in the ground deformation data which was observed during 2012-2015 (Figure 5, Delgado et al., 2016; Evillades et al., 2017). The similarity in the deformation pattern between the 2012-2015, 2016-2017 and 2017-2019 pulses of uplift suggest that the three are produced by magma injection in the same reservoir, although the time series does not show evidences of exponential signals (Figure 4). On the other hand, viscoelastic relaxation produced by transient pressurization followed by stress relaxation in a viscous shell surrounding the reservoir was found to be not important during 2012 and 2015 (Delgado et al., 2016). This does not rule

642 out that more complex viscoelastic rheologies (e.g., [Head et al., 2019](#)) or a more realistic
643 pressure functions can explain the data equally well than the magma injection model. Also,
644 this does not rule out that viscoelastic relaxation is important over longer time scales (10-100
645 years).

646 It is also striking that some of these episodes of uplift can be very short, ranging from ~ 6
647 months to several years. However, their episodic nature for both the onset and end of uplift
648 is not predicted by the models of pressure-driven magma injection because they assume
649 that injection is a prescribed boundary condition. The only option is to incorporate some
650 aspect of the internal dynamics of magma reservoirs into these models ([Walwer et al., 2019](#)).
651 [Delgado et al., 2016](#) cited inelastic effects such as conduit clogging to explain the abrupt end
652 of the deformation in 2015, as it occurred before the exponential trend in the data reached
653 a value close to its asymptote ([Figure 5](#)). The factors controlling the transient deformation
654 before the eruption are also relevant. However, the poor temporal resolution of the 2003-
655 2011 data does not allow to resolve the actual onset and end of the episodes of uplift within
656 several months or even years ([Figure 3](#)).

657 Rhyolitic genesis at Cordón Caulle suggests fractional crystallization from basaltic melts
658 ([Gerlach et al., 1988](#); [Singer et al., 2008](#)), raising the questions to whether the InSAR data
659 are sensitive to the composition of the magma injected in the storage level of neutral buoyancy
660 or not. [Delgado et al. 2018](#) used the Poiseuille flow law ([Jaupart, 2000](#)) to infer the magma
661 composition and concluded that the problem is ill-conditioned because the magma viscosity –
662 a proxy for composition, depends on the fourth power of the conduit radius. This parameter
663 is poorly constrained and this uncertainty results in a wide range of magma viscosities
664 spanning many orders of magnitude. Studies on basaltic systems estimate conduit radii of 1-
665 5 m ([Fukushima et al., 2010](#); [Pedersen and Sigmundsson, 2006](#)) and these values indicate that
666 the injected magma at Cordón Caulle must be basaltic. Therefore, at the moment InSAR
667 cannot provide robust constrains on the magma composition during transient episodes of
668 uplift.

669 I infer that successive intrusions in the remarkably stable level of neutral buoyancy at ~ 6
670 km depth result in the coalescence of these magma bodies on time scales of 10-100 kyr,
671 while the individual magma injections during 2003-2019 should not be able to coalesce on
672 these short scales of less than 10 years ([Biggs and Annen, 2019](#)). Therefore, these multiple
673 injections rejuvenate the system thermally but do not interact chemically with each other
674 (e.g., [Morgado et al., 2019](#)). Instead, these individual and small pockets of melt might
675 remain molten and isolated as high melt fraction magma surrounded by the much bigger
676 crystal mush (e.g., [Gansecki et al., 2019](#)). Finally, is it possible that the InSAR data shows
677 evidence of a mush reorganization process that occurs at depths between 4 and 8 km due
678 to volatile exsolution? Here layers of melt can segregate and migrate over multiple levels in
679 the upper crust ([Cashman et al., 2017](#); [Sparks and Cashman, 2017](#); [Sparks et al., 2019](#)). I

680 consider this a plausible situation for the storage depths of 4-9 km and deserves its detailed
 681 analysis. Geophysical imaging like seismic tomography should be able to provide insights
 682 between these scenarios.

683 Despite the 1 m of post-eruptive uplift between March 2012 until April 2019, the likely
 684 injection of magma has not resulted in an eruption. The injection of 0.146 km³ (*Delgado*
 685 *et al.*, 2018) of magma, most likely basalt, is significantly smaller than the co-eruptive volume
 686 change of ~0.6 km³ (*Jay et al.*, 2014; *Delgado et al.*, 2019) and about twice the volume change
 687 of the pre-eruptive sources during 2003-2011. I use the rupture criteria of *Browning et al.*,
 688 2015 to estimate the maximum rupture pressure p_e for an individual episode of magma
 689 injection (Equation 5 - Equation 6).

$$p_e = \frac{\Delta V_m}{V_m \beta} \quad (5)$$

$$V_m = \frac{V_e}{T_0 \beta} \quad (6)$$

690 Here V_m is the volume of the reservoir, V_e is the erupted volume, T_0 is the tensile strength
 691 of the rock, β is the combined reservoir and magma compressibility, p_e is the reservoir
 692 overpressure and ΔV_m is the volume of the injected magma. Assuming an erupted volume
 693 $V_e = 2.2$ km³ that includes the tephra (1 km³), the lava flow and the shallow laccolith (1.2
 694 km³ DRE, *Delgado et al.*, 2019) and an intruded volume $\Delta V_m = 0.145$ km³ during March
 695 2012 and February 2017 and a tensile strength of the rock $T_0 = 20$ MPa, then the maximum
 696 pressurization in the reservoir is $p_e = 1.3$ MPa. Therefore, I hypothesize that it will take
 697 several decades to reach the same failure threshold inferred before the 2011 eruption and with
 698 pulses of episodic injection similar to those observed during 2012-2019. This assumption only
 699 holds if the mechanical conditions on the reservoir are time-invariant which is rarely the case
 700 (e.g., *Carrier et al.*, 2015).

701 6.5 Structural control of an active magma intrusion

702 Cordón Caulle is considered a landmark case of a volcano in the SVZ where the local struc-
 703 tural setting plays a role controlling magma and eruption dynamics (*Lara et al.*, 2004,
 704 2006a,b; *Cembrano and Lara*, 2009; *Wendt et al.*, 2017). By tectonic control I refer to
 705 the structural heritage and not to the current neotectonic characteristics of the SVZ. The
 706 volcanic chain is emplaced on top of a NW-SE regional basement structure that is misori-
 707 ented with respect to the current kinematic regime of the SVZ and could be resheared to
 708 favor magma emplacement by static stress changes triggered by a megathrust earthquake
 709 (e.g., *Lara et al.*, 2006b; *Cembrano and Lara*, 2009). All the vents of the 1921-1922, 1960

710 and 2011-2012 eruptions are located on both the footwall and hanging wall of the inferred
711 normal faults that bound the Cordón Caulle graben, but I have not observed in the InSAR
712 data conclusive evidence for triggered fault slip on any of these structures. *Delgado et al.*,
713 *2016, 2018, 2019* suggested that as co- and post-eruptive deformation sources are elongated
714 in the direction of the local volcanic chain they are tectonically controlled as proposed for the
715 long-term evolution of the volcano (*Figure 4-Figure 5*). Indeed, all the deformation sources
716 except for the 2008-2011 pulse are elongated in the direction of the volcanic chain (*Figure 7*).
717 It is possible that the local structure that produces the NW-SE alignment of Cordón Caulle
718 is a source trap that enhances magma storage at the level of neutral buoyancy of $\sim 4-9$ km,
719 resulting in deformation signals aligned in this direction and rotating the local stress tensor
720 (e.g., *Lara et al., 2006b*). *Wendt et al., 2017* explored the idea that the deformation during
721 the first three days of the eruption was produced by a tectonically controlled dike (*Castro*
722 *et al., 2016*), but none of their dike models provide a significant better fit than two deflat-
723 ing spherical sources. Therefore the role of the local tectonics driving the emplacement of
724 magma into the upper crust and their interaction with local faults (e.g., *Lundgren et al.*,
725 *2017; MacQueen et al., 2020*) is yet to be explored more thoroughly. The absence of triggered
726 fault slip is similar to Laguna del Maule (LdM) where none of the InSAR studies have found
727 any conclusive evidence for triggered fault slip despite the ~ 2.1 m of uplift between 2007
728 and 2016 (*Feigl et al., 2014; Novoa et al., 2019; Zhan et al., 2019*). Very long InSAR time
729 series (≥ 10 years) might resolve such small fault slip signals in the future.

730 **6.6 Lava flow rheology**

731 The key finding of the InSAR dDEMs is that rhyolitic lava flows are counter-intuitively very
732 mobile, in agreement with other observations (*Tuffen et al., 2013; Magnall et al., 2017*). The
733 extreme thickness of the lava flow could not be properly inferred from field observations
734 (*Bertin et al., 2015*), which recorded a thickness 4 times smaller compared to that of the
735 dDEM data (*Castro et al. 2016; Delgado et al. 2019*). This shows that the planimetric
736 approach that assumes a constant thickness to calculate the lava flow volume does not
737 provide reliable results (e.g., *Pedersen et al., 2018*). The TADR during most of the eruption
738 varied between 10 and 150 m^3/s (*Castro et al., 2016; Delgado et al., 2019*) and is much larger
739 than the TADR of much smaller basaltic and dacitic eruptions, which tend to average 0.5
740 - 10 m^3/s (*Poland, 2014*). The high TADR from the extrusion of a very large volume of
741 lava is similar to that of other large basaltic eruptions studied with InSAR-derived dDEMs,
742 including the 2018 Kilauea eruption with ~ 70 DRE m^3/s (*Lundgren et al., 2019*) and the
743 2012-2013 Tolbachik eruption with $\sim 100-400$ m^3/s (*Kubanek et al., 2017*). This implies
744 that the rhyolite viscosity during the effusive phase was as low as it can be according to
745 theoretical models (*Castro et al., 2013*) or the conduit radius was very wide. On the other
746 hand, the lava flow subsidence rate of $\sim 1.2-1.4$ m/yr is quite fast compared with other

747 subsiding lava fields (*Ebmeier et al., 2012; Carrara et al., 2019*) and four years after the end
748 of the eruption the lava flow displayed a complex pattern of subsidence and motion in the
749 range direction (*Figure 6*). Future studies should consider the rhyolite rheology (*Fink, 1980*)
750 to better explain these observations as well as other data (*Tuffen et al., 2013; Farquharson*
751 *et al., 2015; Magnall et al., 2017*).

752 **6.7 Coupling between the magmatic and hydrothermal system**

753 Cordon Caulle hosts the largest hydrothermal system of the SVZ (*Sepulveda et al. 2004,*
754 *2007*), with five fumarolic fields (*Figure 1*) which are likely to be coupled to the magmatic
755 system of the volcano. The role of the hydrothermal system to produce ground deforma-
756 tion has been considered to be negligible with respect to the magmatic system because the
757 InSAR-derived sources of deformation are much deeper than those inferred for the hydrother-
758 mal system (*Jay et al. 2014*). The only exception is the uplift recorded near the Trahuilco
759 geyser inside Cordillera Nevada (*Figure 1*). This area deformed right after the 2010 Maule
760 earthquake (*Figure 3d*) and the source model is 2-3 times shallower than the rest of the
761 deformation sources, ruling out a magmatic origin. The spatial coincidence between deforma-
762 tion, the dynamic triggering by the earthquake and an hydrothermal system suggest that
763 the passage of seismic waves produced transient changes in permeability that can induce
764 groundwater flow resulting in ground deformation (e.g., *Manga et al. 2012; Pritchard et al.*
765 *2013*).

766 The large amount of hydrothermal vents in the volcano suggests that the previous argument
767 to neglect the role of the hydrothermal system on modulating the episodes of unrest is too
768 simplistic. For example, *Chang et al., 2007* have shown that magma injection in sills can
769 induce the flow of magmatic brines between multiple sources of deformation below Yellow-
770 stone caldera. Also, pressurization in hydrothermal systems can produce ground deformation
771 signals that resemble those of magmatic origin (e.g., *Hurwitz et al., 2007*). *Pritchard et al.,*
772 *2019* have shown that time-lapse gas monitoring and microgravity measurements can reduce
773 the ambiguity on the driving mechanisms of ground deformation but unfortunately neither
774 have ever been attempted at Cordon Caulle. Further, at the time of writing no detailed anal-
775 ysis have been carried out on the volcano hydrothermal vents after the 2011-2012 eruption.
776 Future studies should consider to what extent the hydrothermal and the magmatic system
777 are coupled.

778 6.8 Comparison with other systems

779 6.8.1 Eruption triggering

Journal Pre-proof

780 The triggering mechanism of the 2011-2012 eruption is a matter of debate as described ear-
781 lier. Similar situations were observed at Eyjafjallajökull, Grímsvotn and Okmok volcanoes
782 that have repeatedly displayed ground deformation before several eruptions despite the dif-
783 ferences in magma composition and tectonic setting between the SVZ, the North Atlantic rift
784 and Aleutians subduction zone. At Eyjafjallajökull, InSAR detected transient pulses of uplift
785 interpreted as magma intrusion that occurred more than 10 years and a few months before its
786 2010 eruption (*Pedersen and Sigmundsson, 2006; Hooper, 2008; Sigmundsson et al., 2010*),
787 with a potential eruption triggering due to lateral stress change (*Albino and Sigmundsson,*
788 *2014*). At Grímsvotn, GPS data have recorded two cycles of pre-eruptive uplift with expo-
789 nential trends indicative of magma injection leading to two eruptions (*Reverso et al., 2014;*
790 *Bato et al., 2018; Sigmundsson et al., 2018*). At Okmok, InSAR has also recorded cycles
791 of co-eruptive subsidence and pre and post-eruptive uplift that follow exponential trends
792 indicative of magma injection and extrusion (*Lu et al., 2010; Lu and Dzurisin, 2010, 2014;*
793 *Biggs et al., 2010*). These examples suggest that to some extent the geodetic signals that
794 can be observed on yearly to decadal time scales during cycles of magmatic unrest and erup-
795 tion are independent of the tectonic setting and of the chemical composition of the erupted
796 magma.

797 6.8.2 Eruption dynamics

798 The InSAR observations of co-eruptive deformation are difficult to compare with other sim-
799 ilar events due to the lack of other rhyolitic eruptions with instrumental observations. The
800 2008-2009 dome-forming eruption of Chaiteén volcano is the only one of these events and
801 was triggered by a dike intrusion (*Fournier et al., 2010; Wicks et al., 2011*), resulting in a
802 very asymmetric different deformation signal compared to that of Cordón Caulle. In terms
803 of its temporal evolution, ground deformation was negligible during more than half of the
804 eruption (*Pina-Gauthier et al., 2013; Reath et al., 2019*) and the dome extrusion followed an
805 exponential trend for the first three months while during the rest of the eruption there is
806 no constraining data (*Pallister et al., 2013*). Therefore it is not clear how representative are
807 the deformation signals of the 2011-2012 eruption of other rhyolitic eruptions. In terms of
808 the co-eruptive ground deformation and extruded volume, similar exponential signals were
809 recorded at Mt St. Helens (*Anderson and Segall, 2013*) and Sinabung (*Hotta et al., 2017;*
810 *Nakada et al., 2017*) volcanoes for both types of data.

811 6.8.3 Transient uplift

812 In general deformation rates larger than 20 cm/yr are rare in subduction zone volcanoes (e.g.,
813 *Fournier et al., 2010; Henderson and Pritchard, 2013*) and Cordón Caulle has had these rates
814 at least three times. The only equivalent system is Laguna del Maule (*Feigl et al., 2014; Le*
815 *Mével et al., 2015*) with a maximum of 28 cm/yr, which is still $\sim 50\%$ less than the maximum
816 of 45 cm/yr recorded in 2012. Other rhyolitic volcanoes like Yellowstone (*Chang et al., 2007;*
817 *Dzurisin et al., 2012; Tizzani et al., 2015*) and Long Valley (*Montgomery-Brown et al., 2015*)
818 have much lower satellite-detected deformation rates of 1-10 cm/yr. Compared with other
819 rhyolitic systems, transient changes in the ground deformation that occur on time scales of
820 ~ 0.5 -1 years are much faster at Cordón Caulle than at the aforementioned, so fast that they
821 are akin to those observed at basaltic calderas (e.g., *Poland et al., 2012*). Changes in the
822 uplift rate at Yellowstone (*Dzurisin et al., 2012*) and Laguna del Maule (*Le Mével et al., 2015*)
823 have been related to seismic swarms, but they have never been observed at Cordón Caulle
824 (*Delgado et al., 2018*). Therefore, Cordón Caulle can be considered a quite anomalously fast
825 deforming volcano for both the uplift velocity and the transition from quiescence to unrest
826 and back to quiescence.

827 6.9 An integrated view from InSAR, petrology and field observa- 828 tions

829 **Figure 9** summarizes my geological interpretation on the plumbing system of Cordón Caulle
830 for the time period between March 2003 and May 2020. The volcano is underlain by a
831 laterally extensive plumbing system that extends from Cordillera Nevada caldera to Puyehue
832 volcano, which is a crystal mush with melt-rich pockets that segregate to the liquid-rich
833 cap on top of the mush through compaction and other mechanisms (e.g., *Bachmann and*
834 *Bergantz, 2006*). In the absence of data other than InSAR, I suggest that ground uplift
835 results from basalt injection into the crystal mush, potentially triggering melt extraction,
836 although the exact details cannot be inferred with the existing data. Magma injections likely
837 occurred during 2003-2007, 2007-2008, 2008-2011 and scattered across the volcanic chain.
838 During the onset of the eruption, two reservoirs located below Cordillera Nevada caldera
839 and Puyehue volcano deflated during the first three eruption days. During the rest of the
840 eruption, a single reservoir deflated, and coeval with lava effusion and a shallow laccolith
841 intrusion. These three reservoirs drained distinct areas of the plumbing system of the volcano.
842 Afterwards, three pulses of likely magma injection were intruded in the same area from
843 where magma was intruded before the eruption and drained during the effusive phase of
844 the eruption. In general, all the deformation sources lie at depths between 4 and 9 km,
845 with no InSAR nor petrological evidence for deeper sources (*Castro et al., 2013; Jay et al.,*
846 *2014*). Hence, unrest does not occur at multiple levels throughout the crust and I consider

847 this volcano to be a translateral instead of a transcrustal magmatic system (*Cashman et al.*,
848 2017; *Sparks et al.*, 2019), with likely stress interactions between the sources. By translateral
849 I imply that unrest occurs in multiply places along the laterally extensive shallow plumbing
850 system.

851 7 InSAR technological challenges

852 Although the InSAR data availability at Cordón Caulle has increased exponentially in the
853 past decade, significant technical challenges remain in this area for a wider use of InSAR.
854 These challenges are the limited and non-ideal data coverage and systematic coherence loss.

855 7.1 Data availability

856 During most of 2003-2012, descending SAR images that would result in coherent interfero-
857 grams were seldom available and only since May 2013 CSK brought ascending and descending
858 acquisitions to the same temporal resolution. Data from the current TSX, CSK, RS2, S1
859 and ALOS-2 missions have been acquired with different degrees of temporal resolution at the
860 volcano. TSX data were only systematically acquired during the onset of the eruption, but
861 not during the end and during the post-eruptive uplift. CSK data are the most consistently
862 acquired data to date in the volcano, with a time series that spans between March 2012 and
863 August 2020. RS2 data have been acquired with four different stripmap beams during the
864 eruption and the sequence of post-eruptive uplift. This has allowed to compare the quality
865 of these modes and beams (*Pritchard et al.*, 2018), but at the same time has hampered the
866 systematic acquisition of a long time series. S1 data were acquired every 24 days between Oc-
867 tober 2014 until February 2017 when the mission started to acquire data every 12 days in the
868 descending track. However ascending acquisitions were then stopped until November 2018
869 when they were restarted every 6 days after a special request to the European Space Agency.
870 Afterwards they were reduced to every 12 days in June 2019. ALOS-2 acquired ScanSAR
871 data every 42 days since burst synchronization was achieved in February 2015. However,
872 the temporal sampling was decreased to ~ 4 SLCs/year in September 2017 for crustal defor-
873 mation applications in accord with the mission basic observation scenario. This resulted in
874 only 3 non-winter ScanSAR SLCs during December 2017 and February 2020 per track, with
875 no predicted acquisitions in this mode during 2020. Further, ALOS-2 stripmap data have
876 never been acquired with a better temporal sampling than 2 SLCs per year per track. With
877 such a poor temporal sampling it is currently not possible to track time-dependent processes
878 at Cordón Caulle with L-band data. On the other hand, if another eruption were about to
879 occur, it would not be possible to calculate a co-eruptive time series of dDEM because TDX
880 is no longer acquiring bistatic data in this region. The alternative to construct dDEMs is

881 to use stereo optical data like Pléiades, SPOT and WorldView, but they do not have the
882 required temporal resolution to construct these time series (less than 6 months) and they
883 are also limited by the clouds ([Delgado et al., 2019](#)).

884 7.2 Coherence

885 The biggest drawback for a better use of InSAR at Cordón Caulle is the coherence loss
886 due to its alpine conditions and thick temperate rain forest that surrounds the volcano. In
887 my experience, the coherence loss is very fast compared with vegetated volcanoes in similar
888 environments elsewhere like Yellowstone. Depending on the year, the snow hampers the
889 use of InSAR between 5 and 7 months, usually from mid-late May to mid-late November.
890 Therefore, it has not been possible to measure ground deformation in the winter on top of
891 the volcano, even with 1-day CSK interferograms ([Delgado et al., 2018](#)), although ALOS-2
892 ScanSAR data were promising in this aspect ([Euillades et al., 2017](#)). Further, small baseline
893 interferograms can have very low coherence even in the summer. In general, the coherence
894 loss precludes the data processing in a rigorous small baseline fashion, i.e., to use all the
895 interferograms that share an image as reference that have a temporal baseline shorter than a
896 given threshold, usually shorter than two months ([Figure 10](#)). Thereby advanced time series
897 algorithms that rely on an interferometric network with good connectivity (e.g., [Yunjun
898 et al., 2019](#)) cannot be used at Cordón Caulle. The environmental conditions of the volcano
899 and the fast deformation rates make L-band data the ideal platform to measure ground
900 deformation. However, as described earlier the temporal resolution of ALOS-2 has always
901 been far from ideal and it is unlikely that L-band data availability will improve until the
902 launch of the NASA NISAR mission in 2022.

903 In terms of legacy data, by far the most useful ENVISAT data are from its extension mission
904 during 2011-2012 – the only time when the mission acquired data during every overflight.
905 This data were acquired by the IM6 beam, not the standard IM2 of the satellite nominal
906 mission. The main differences between the IM6 extension mission data compared with that
907 of IM2 nominal mission are a repeat period of 30 vs 35 days, HH instead of VV polarization,
908 a look angle of 45° instead of 23° and a good orbital control for small baseline interfero-
909 grams despite the orbit drift. All of these conditions resulted in acquisitions of much better
910 quality during the extension mission than in the nominal mission (e.g., [Delgado et al., 2017](#);
911 [Pritchard et al., 2018, Figure 4](#)). The ENVISAT IM2 acquisitions were always limited by
912 the poor orbital control at the beginning of the mission, lack of data after 2006 and the
913 potential drawback of the VV polarization ([Pritchard et al., 2018](#)) resulting in very few use-
914 ful interferograms ([Figure 3a-b](#)). On the other hand, the ALOS-1 acquisition program was
915 always far from ideal, with a temporal resolution of ~ 2 -3 images per track in the austral
916 late spring, summer and early fall. Had ALOS-1 lasted for two additional months before
917 its failure in April 2011, just two months before the eruption, the quality of the L-band

918 co-eruptive interferograms would be excellent and coherent observations would be available
919 near the eruptive vent.

920 X-band processing at Cordón Caulle is challenging and tedious due to the rapid coherence
921 loss and large volumes of data. Therefore it is not possible to sustain the coherence in the
922 vegetated flanks of the volcano in early fall to late summer CSK interferograms which are
923 required to ensure the connectivity of the InSAR network (e.g., *DeGrandpre et al., 2019*).
924 In the absence of GPS data, the only solution I have envisioned to remove ramps and to
925 reference the CSK interferograms to a non-deforming area is to calculate a preliminary
926 source model inverted from good quality ascending and descending interferograms, fix the
927 geometry of this model, invert every CSK interferogram for its source strength and a ramp
928 and then subtract the latter to the data (*Delgado et al., 2016*). The situation can be even
929 more problematic due to the orbit drift of the mission, resulting in a 2 km difference in the
930 perpendicular baseline between SLCs acquired in early 2012 and those from 2019. Further,
931 images that are acquired a few days apart from each other can have perpendicular baselines
932 well beyond the critical baseline. The real value of CSK in this volcano is that a descending
933 track is the only data set that has recorded in its entirety the sequence of ~ 1 m of uplift
934 (*Figure 5a-d*). On the other hand TSX data were only acquired in a systematic way during
935 the onset of the eruption in 2011. The coherence of these austral winter interferograms is
936 extremely low, but they still recorded deformation. The lack of other TSX data hampers a
937 direct comparison with the coherence of the CSK data.

938 The quality of the S1 data at Cordón Caulle has been less than ideal, in part due to data gaps
939 and low coherence even in the austral summer despite the 12 day repeat period. It is also not
940 straightforward to select summer to summer interferograms to connect the non-winter small
941 baseline sets of interferograms (*Figure 10*). *Pritchard et al., 2018* found that the coherence
942 of S1 is lower than the coherence of RS2 Wide Ultra Fine (WUF) interferograms because the
943 resolution of the latter is one order of magnitude better than the resolution of the S1 TOPS
944 mode and the RS2 HH instead of the S1 VV polarization. Despite the unrivalled benefits
945 that S1 has provided to the volcano and active tectonics InSAR communities (e.g., *Funning
946 and Garcia, 2019*), due to the aforementioned issues I do not consider that S1 data have
947 significantly contributed to a better understanding of magma dynamic at Cordón Caulle.
948 However this situation might change with the lack of ALOS-2 data, potential lack of access
949 to RS2 data and the huge baseline drift of CSK, making S1 the most reliable source of InSAR
950 data in the area in the future. If an eruption were to occur in the winter, it is likely that
951 near-field measurement will only be possible with the GPS stations located on top of the
952 volcano (*Figure 5*).

953 Considering the time scales of most of the magmatic processes at Cordón Caulle and the
954 coherence and temporal resolution of each data, currently the best suited data to study
955 ground deformation at this volcano are the RS2 WUF beams. However, in my experience

956 InSAR users should rely on the whole civilian constellation of SAR data, because each of
957 these aforementioned platforms have several advantages and drawbacks and using all of them
958 can improve the temporal sampling of individual platforms.

959 **8 Conclusions**

960 In this golden era of InSAR it is impressive how much the technology and the resulting
961 amounts of data have evolved since the ENVISAT mission in the early 2000's leading to
962 outstanding discoveries like the aforementioned sequence of unrest between 2003 and 2020.
963 Many aspects remain to be elucidated from the Cordón Caulle dynamics and here is where I
964 envision that the wealth of InSAR data that will be provided by the next generation InSAR
965 missions (NISAR, Sentinel-1C/D, TanDEM-L, RADARSAT constellation, CSK Second Gen-
966 eration, SAOCOM-1A) will improve our understanding of volcano dynamics like ENVISAT
967 and COSMO-SkyMED did at the beginning of the previous decades. I envision that many of
968 the issues with the lack of data and coherence loss could be solved with a better collaboration
969 between the multiple space agencies, resulting in acquisitions with higher temporal resolu-
970 tion and the best data characteristics (e.g., polarization) for the environmental conditions
971 of the volcano.

972 In general InSAR has been an excellent tool to detect episodic pulses of ground deformation
973 that I have related to magma injection given the lack of other constraining data and there
974 is little doubt that the detection capability will improve with the future missions. Since
975 Cordón Caulle has been a restless volcano for most of the whole 2003-2020 period, it is very
976 likely than in the near future it will deform again providing new and exciting discoveries.
977 Despite the InSAR technological advances, the geological interpretation of geodetic signals
978 has not evolved as nearly as fast. In my opinion the most significant scientific question from
979 a volcano geodesy perspective that must be addressed at Cordón Caulle is what magmatic
980 and hydrothermal processes produce ground deformation signals? Geophysical data in gen-
981 eral do not have resolution to resolve for the detailed structures of interest in plumbing
982 systems. Therefore, I envision that more realistic models of ground deformation are required
983 to assess whether InSAR data can be explained by models of magma injection or some other
984 mechanism of unrest including volatile exsolution and melt reorganization inside of a crystal
985 mush.

986 **Acknowledgements**

987 This review is the result of discussions and collaborations with many colleagues in the world
988 in the past six years. I thank the French Centre National d'Etudes Spatiales (CNES) for a

989 postdoctoral fellowship, Editor Pablo Euillades for the invitation to participate in this special
990 issue, A. Pérez-Fodich (Institut de Physique du Globe de Paris) for suggesting the idea to
991 write this review article, and many colleagues who in one way or the other have contributed
992 with either data, software, ideas or comments to a better understanding of the dynamics of
993 Cordón Caulle. These include Matthew Pritchard, Jennifer Jay, Whyjay Zheng (Cornell Uni-
994 versity), Paul Lundgren (Jet Propulsion Laboratory, Caltech/NASA), Julia Kubanek (ES-
995 TEC, European Space Agency), Kyle Anderson (California Volcano Observatory, U. S. Ge-
996 ological Survey), Michael Poland (Cascades Volcano Observatory, U. S. Geological Survey),
997 Simona Zoffoli (Agenzia Spatiale Italiana), Sergey Samsonov (Canada Centre for Mapping
998 and Earth Observation, Natural Resources Canada), Diego Coppola (Università di Torino),
999 Philippe Ruprecht, Heather Winslow (University of Nevada, Reno), Helge Gonnermann,
1000 Patrick Phelps (Rice University), Carolina Muñoz (Universidad de Chile), Juliet Biggs, Fa-
1001 bien Albino (University of Bristol), Loreto Córdova, Daniel Basualto, Daniel Bertin, Luis
1002 Lara (SERNAGEOMIN), Tara Shreve, Raphaël Grandin (Institut de Physique du Globe
1003 de Paris), Hugh Tuffen (University of Lancaster), and Camila Novoa (Géosciences Environ-
1004 nement Toulouse). Finally I acknowledge the two anonymous reviewers whose comments
1005 improved the quality of this study. ENVISAT images were provided by the European Space
1006 Agency (ESA) and Level 1 SLC images are available at the [ESA On-The-Fly](#) site. ALOS-1
1007 data are property of Japanese Aerospace Exploration Agency (JAXA) and the Japanese
1008 Ministerium of Trade and Commerce and are available at the [Alaska Satellite Facility](#) by
1009 NASA. Sentinel-1A/B SLC data were provided by ESA and distributed by [Alaska Satellite](#)
1010 [Facility](#) and [CNES PEPS](#). TerraSAR-X data were provided by Deutsches Zentrum für Luft-
1011 und Raumfahrt (DLR) through the scientific quota available to the CEOS Latin Amer-
1012 ica Volcano Pilot Project (CLAPP) coordinated by Michael Poland (USGS) and Simona
1013 Zoffoli (ASI) (*Pritchard et al., 2018*). COSMO-SkyMED data were provided by Agenzia
1014 Spatiale Italiana (ASI) through CLAPP. RADARSAT-2 data were provided by Canadian
1015 Space Agency (CSA) and MacDonald, Dettwiler & Associates (MDA) Ltd. through CLAPP
1016 and the SOAR-EI project #5437. TanDEM-X DEMs and CoSSC data were provided by
1017 DLR through the DEM proposals #DEM_GEOL2437 and NTLINSA0405. The GPS data
1018 were provided by OVDAS-SERNAGEOMIN and are available upon request through the [Por-
1019 tal Transparencia](#) platform. The processed data sets and intermediate products are available
1020 upon request to the author except for RADARSAT-2 data which are not available for open
1021 distribution under the license agreement of MDA. Several figures were created with the GMT
1022 software (*Wessel and Smith, 1998*).

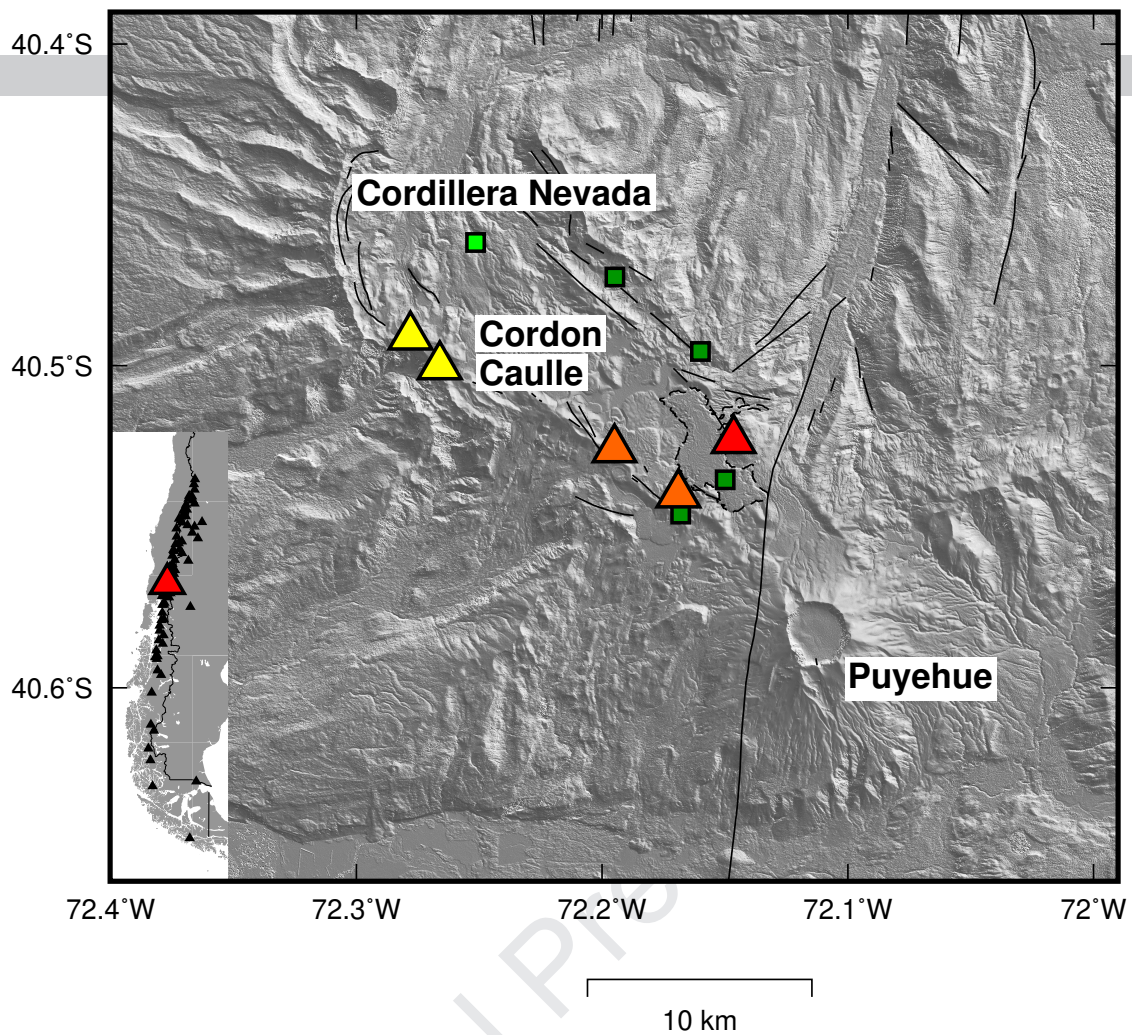

Figure 1: Cordón Caulle location map draped over the 12 m TanDEM-X shaded topography. The yellow, orange and red triangles are the 1921-1922, 1960 and 2011-2012 eruptive vents. The black dashed outline is the 2011-2012 lava flow and the black lines are faults (*Jay et al., 2014*). Green squares are hot springs and fumaroles and the light green square is the Trahuilco geyser (*Sepulveda et al., 2004*). All the eruptive vents are located in the NW-SE direction faults that bound the Cordón Caulle graben. The inset shows the location within South America, where the black and red triangles are Holocene volcanoes and Cordón Caulle.

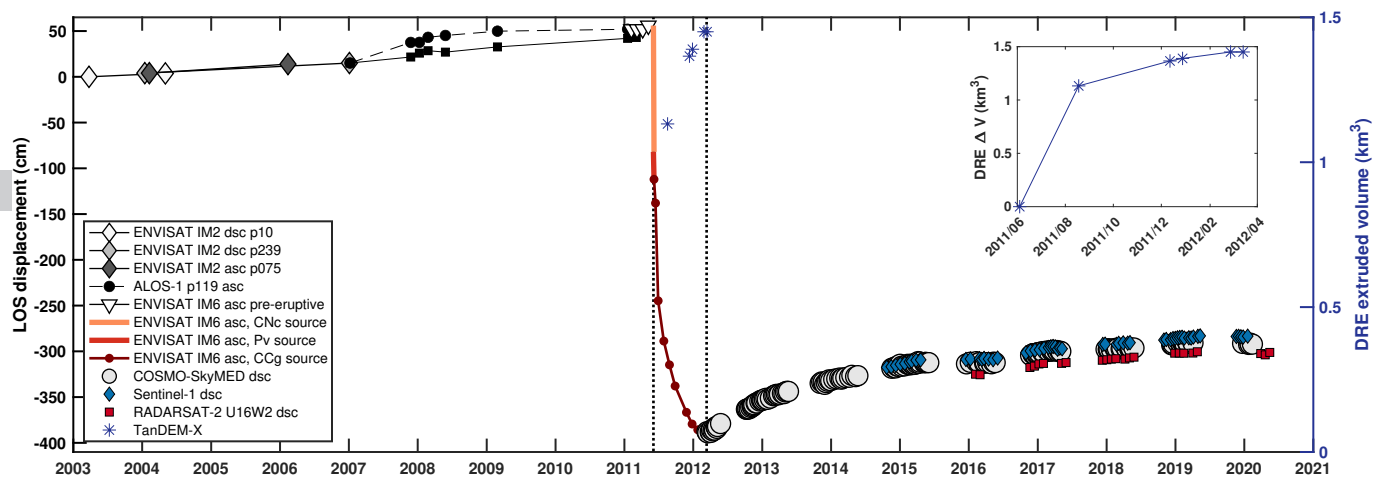

Figure 2: Compilation of line-of-sight (LOS) ground displacement from InSAR time series between 2003 and 2020 for selected pixels, including the 2011-2012 eruption (vertical dashed lines). The figure combines data from different orbits and viewing geometries because there is no single data that spans the whole sequence of unrest. The different data sets have been shifted by a constant so they lie approximately on top of each other for a better visual comparison. This also give the time series a qualitative continuity. Data location in Figure 3a-b and Figure S1 for ENVISAT IM2 (Image Mode 2) 2003-2007, Figure 3c,d for ALOS-1 2007-2011, Figure 3e for ENVISAT IM6 (Image Mode 6) pre-eruptive, Figure 4a,b for ENVISAT IM6 CNC (Cordillera Nevada caldera), Pv (Puyehue volcano) and CCg (Cordón Caulle graben) sources, Figure 6a,g,h for COSMO-SkyMED, Sentinel-1 and RADARSAT-2. Asc/dsc refers to ascending and descending data respectively. p10, p239, p075 and p119 refers to ENVISAT IM2 paths 10, 239 075 and ALOS-1 path 119. ENVISAT IM6 pre-eruptive time series by *Reath et al., 2019*. COSMO-SkyMED, RADARSAT-2 and Sentinel-1 time series updated from *Delgado et al., 2018*. Right axis and inset show dense rock equivalent (DRE) lava flow extruded and laccolith intruded volume from TanDEM-X differential DEMs (*Delgado et al., 2019*). ENVISAT IM6 time series for CNC and Pv sources were calculated adding the maximum displacement produced by each one as recorded in Figure 4a. ENVISAT IM6 time series for CCg source was calculated for the point of maximum LOS predicted by the best-fit prolate spheroid model because there is no coherence on top of the volcano during more than half of the eruption (*Delgado et al., 2019*).

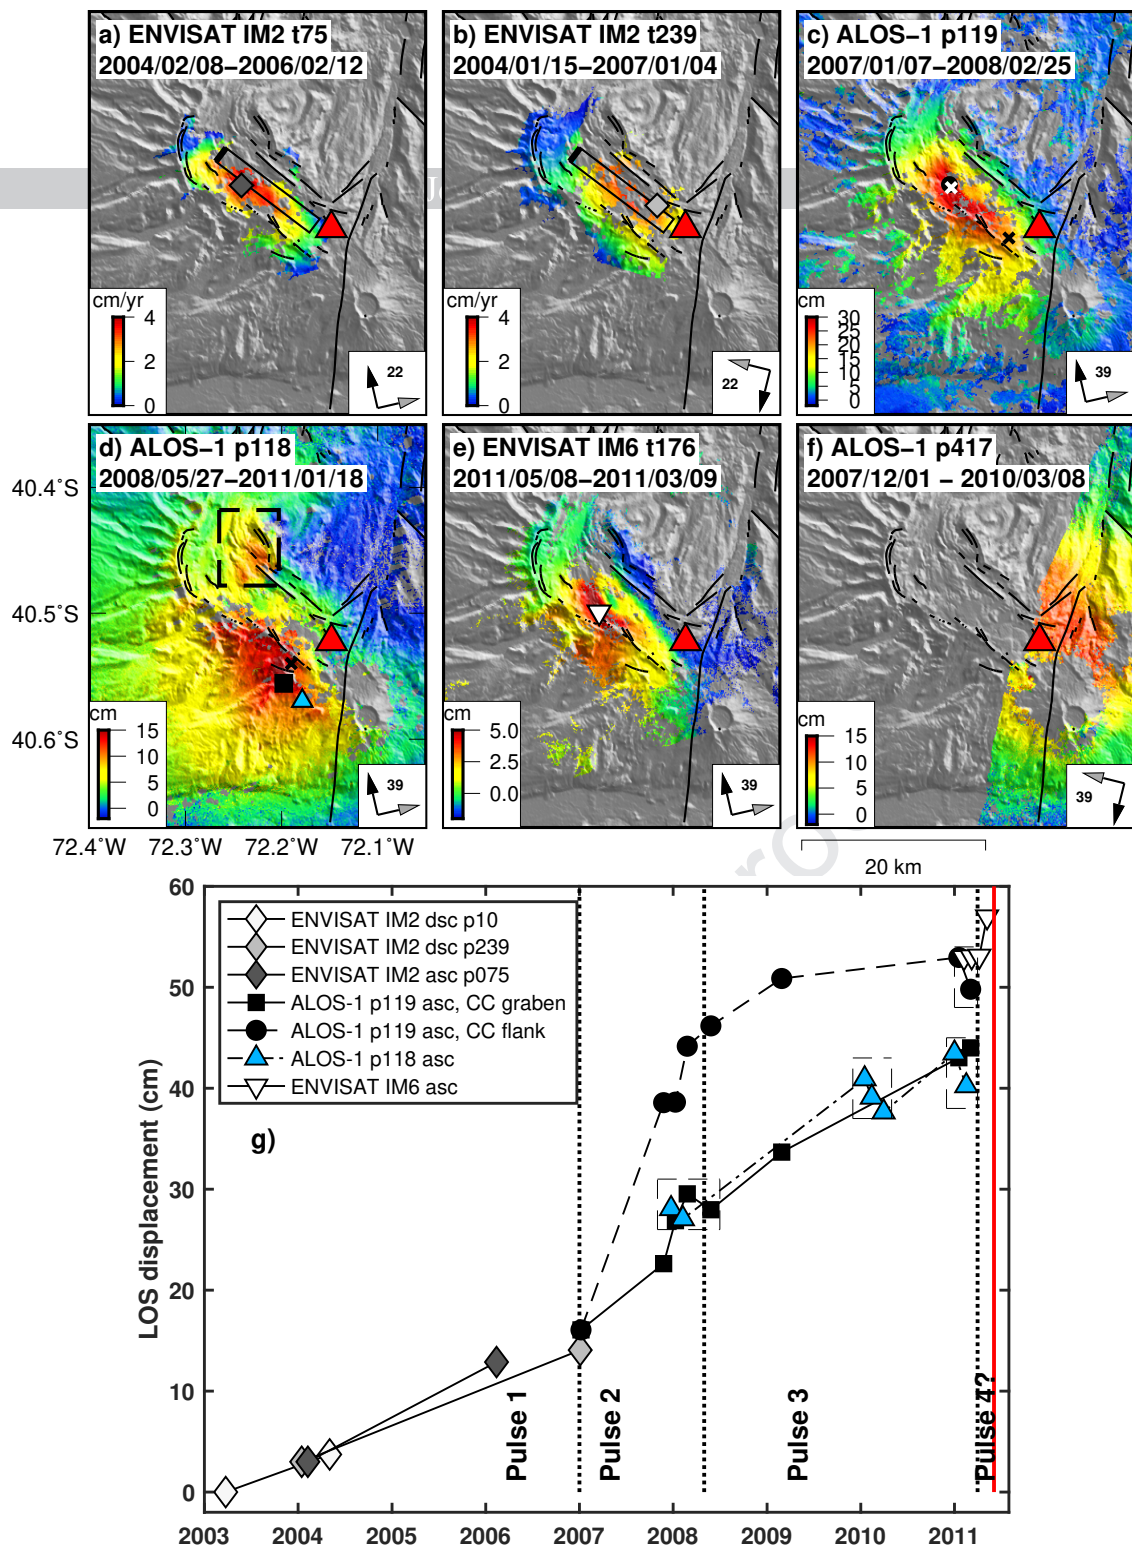

Figure 3: Summary of InSAR observations of pre-eruptive LOS uplift between 2003 and 2011. a-f). All panels show LOS ground deformation with the respective deformation sources and the 2011-2012 eruptive vent (red triangle). a-b) show interferograms converted to mean ground velocity while c-f) show the cumulative ground deformation. In each panel the black and grey arrows show the satellite heading and horizontal component of the LOS vector. The number next to the arrows is the look angle. a-b) First pulse of uplift during 2003-2007 with a rate of $\sim 3\text{-}4$ cm/yr. The black square is the contour of the best-fit sill model. c) Second pulse of uplift during 2007-2008 with a total displacement of ~ 30 cm. The crosses show the best-fit Mogi sources. d, f) Third pulse of uplift during 2008-2011 with a total displacement of ~ 15 cm. The dashed line is the area near the Trahuilco geyser in February - March 2010 that uplifted likely triggered by the 2010 Maule earthquake. The cross shows the best-fit pressurized Mogi source. e) Potential fourth pulse of uplift during early 2011 with a total displacement of ~ 5 cm. f) Descending ALOS-1 interferograms that shows the end of the second pulse of uplift and the third pulse of uplift. g). Time series of ground deformation calculated for the pixels of the same color and symbol in the upper panel and Figure 2. The time series were shifted by an arbitrary constant as in Figure 2. Rate map for ALOS-1 p118 asc is not shown in the figure. ENVISAT IM6 time series for early 2011 by *Reath et al., 2019*. The dashed lines show localized atmospheric signals that are non-stationary across the scene, and therefore cannot be corrected with an empirical correction that correlates the phase and the topography across the interferogram.

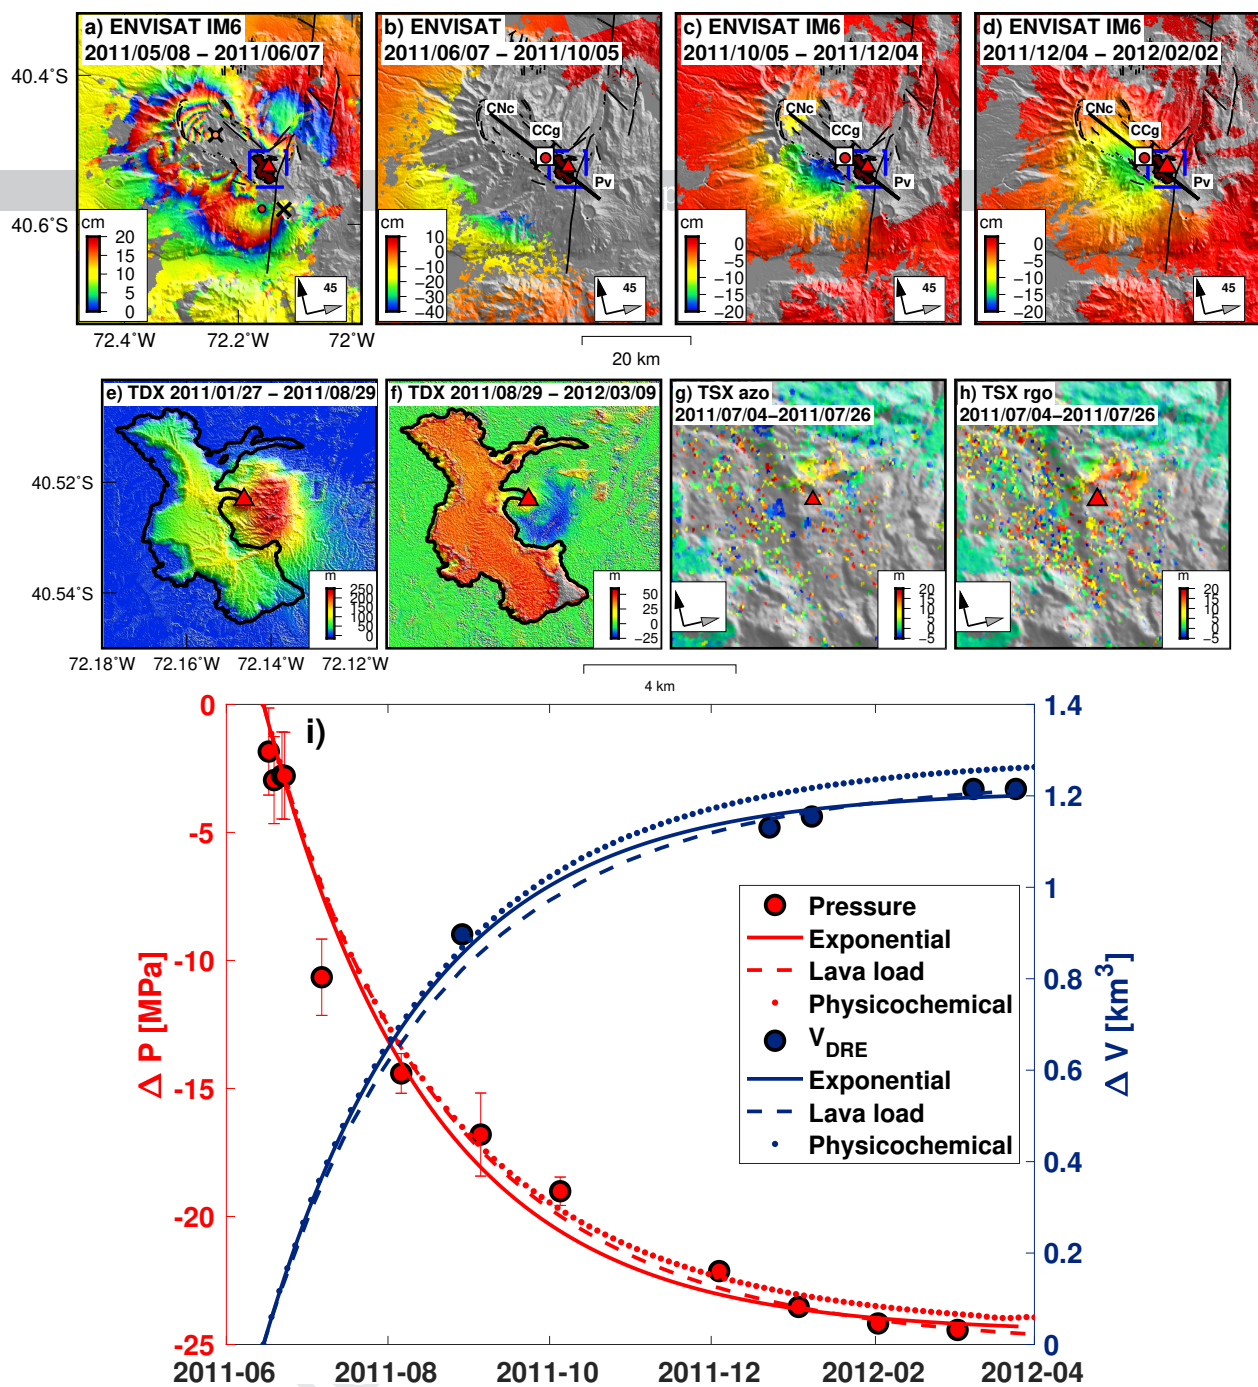

Figure 4: Summary of InSAR observations of subsidence during the 2011-2012 eruption. a-d) Ground subsidence recorded by four ENVISAT interferograms. The data span the first three days of the eruption (a) (modified from [Jay et al., 2014](#)), day three to 4 months (b) (modified from [Jay et al., 2014](#)), four to six months (c), six to eight months (d). Interferogram a) is presented wrapped with one fringe equivalent to 20 cm of ground deformation to highlight ~ 1.3 m and ~ 0.3 m of subsidence at Cordillera Nevada caldera (CNc) and Puyehue volcano (Pv). The best-fit Mogi sources for a) are the two black crosses circles and the best-fit Yang source for b-d) is the white square with the black thick lines that show the spheroid semi-major and minor axes. The circles in a) and the red circle in b-d) show the location of the time series in [Figure 2](#). The red triangle is the eruptive vent. The dashed blue square shows the area of e-h). TanDEM-X differential DEMs that span from the beginning of the eruption to August 2011 (e) and August 2011 to March 2012 (f). Azimuth (azo, g) and range offsets (rgo, h) that record more than 10 m of post-emplacment deformation in the area of the shallow laccolith. i) Time series of pressure drop (red circles) and intruded laccolith and extruded lava flow volume (blue circles) during the effusive phase of the eruption with fits for three different eruption models (modified from Figure 8 of [Delgado et al., 2019](#)). Here exponential refers to an analytic model of reservoir depressurization and lava effusion whose solution is an exponential function ([Equation 1-Equation 2](#)). Lava load is a numerical model that incorporates the effects of the lava load onto the reservoir force balance ([Mastin et al., 2008](#)). Physicochemical is a numerical model that incorporates both the lava load effect and the H₂O and CO₂ exsolution in the reservoir ([Anderson and Segall, 2013](#); [Delgado et al., 2019](#)).

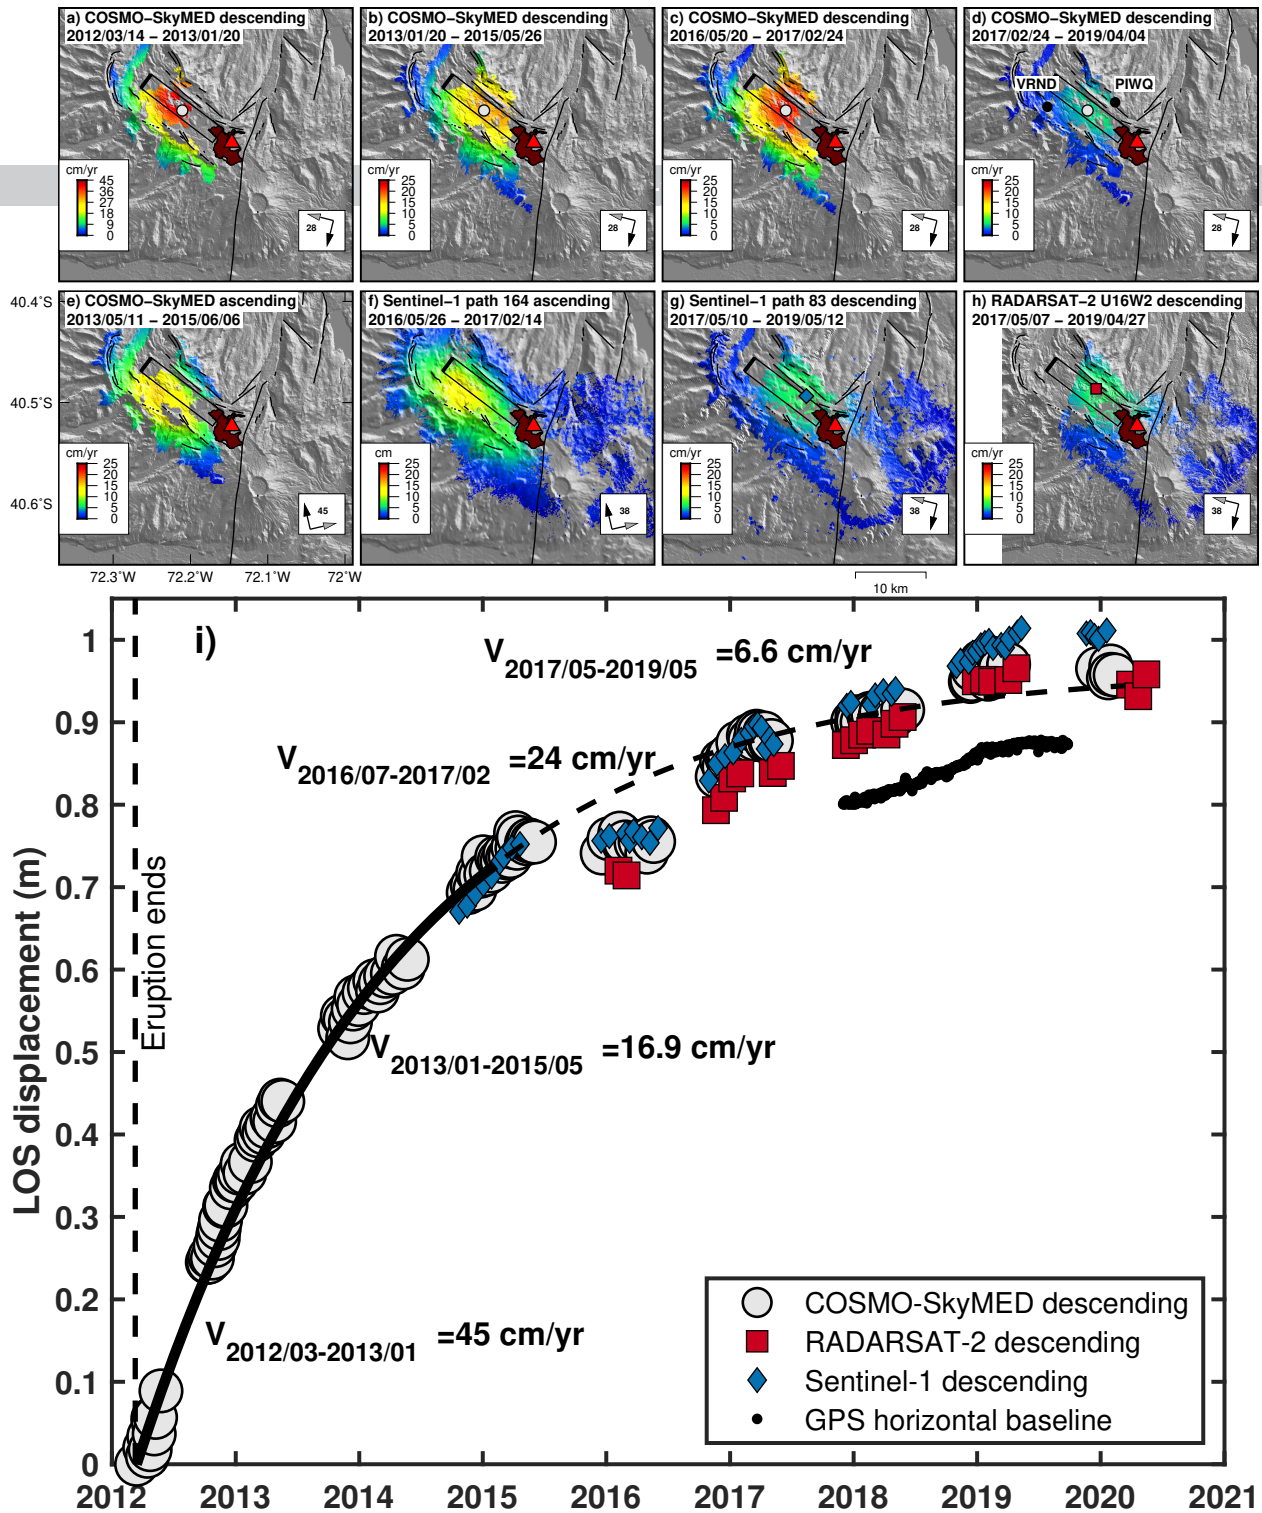

Figure 5: Summary of InSAR observations of post-eruptive LOS ground uplift between 2012 and 2020. Mean ground velocity recorded by a-d) CSK descending 2012-2019, e) CSK ascending 2013-2015, f) S1 ascending 2016-2017, g) S1 descending 2017-2019 and h) RS2 descending 2017-2019. Data in a,b,e) from [Delgado et al., 2016](#) and data in c,f) modified from [Delgado et al., 2018](#). d,g,h) show new data. Note that c) and f) cover the same time span, but are plot with different color scales because c) is a mean velocity and f) shows the cumulative displacement during the 6 months of this uplift event. The black rectangle is the best-fit tensile dislocation with uniform opening during the 2012-2017 time span ([Delgado et al., 2016](#)). The black circles in d) are the GPS stations installed in December 2017. The brown outline and the red triangle are the 2011-2012 lava flow and eruptive vent respectively. i) Descending time series of ground deformation for selected pixels for CSK (grey circles in a-d), S1 (blue diamond in g) and RS2 (red square in h). The data shows three pulses of uplift during March 2012 - May 2015, July 2016 - February 2017 and May 2017 - May 2020. The data sets have been shifted by an arbitrary constant so they approximately lie on top of each other to simplify the geologic interpretation. The GPS data are the horizontal baseline change between the two stations located on both sides of the volcano (d). The black thick line is an exponential fit to the 2012-2015 CSK data and is indicative of magma injection. The dashed black line is the exponential fit to the 2012-2015 CSK data extrapolated until 2020.

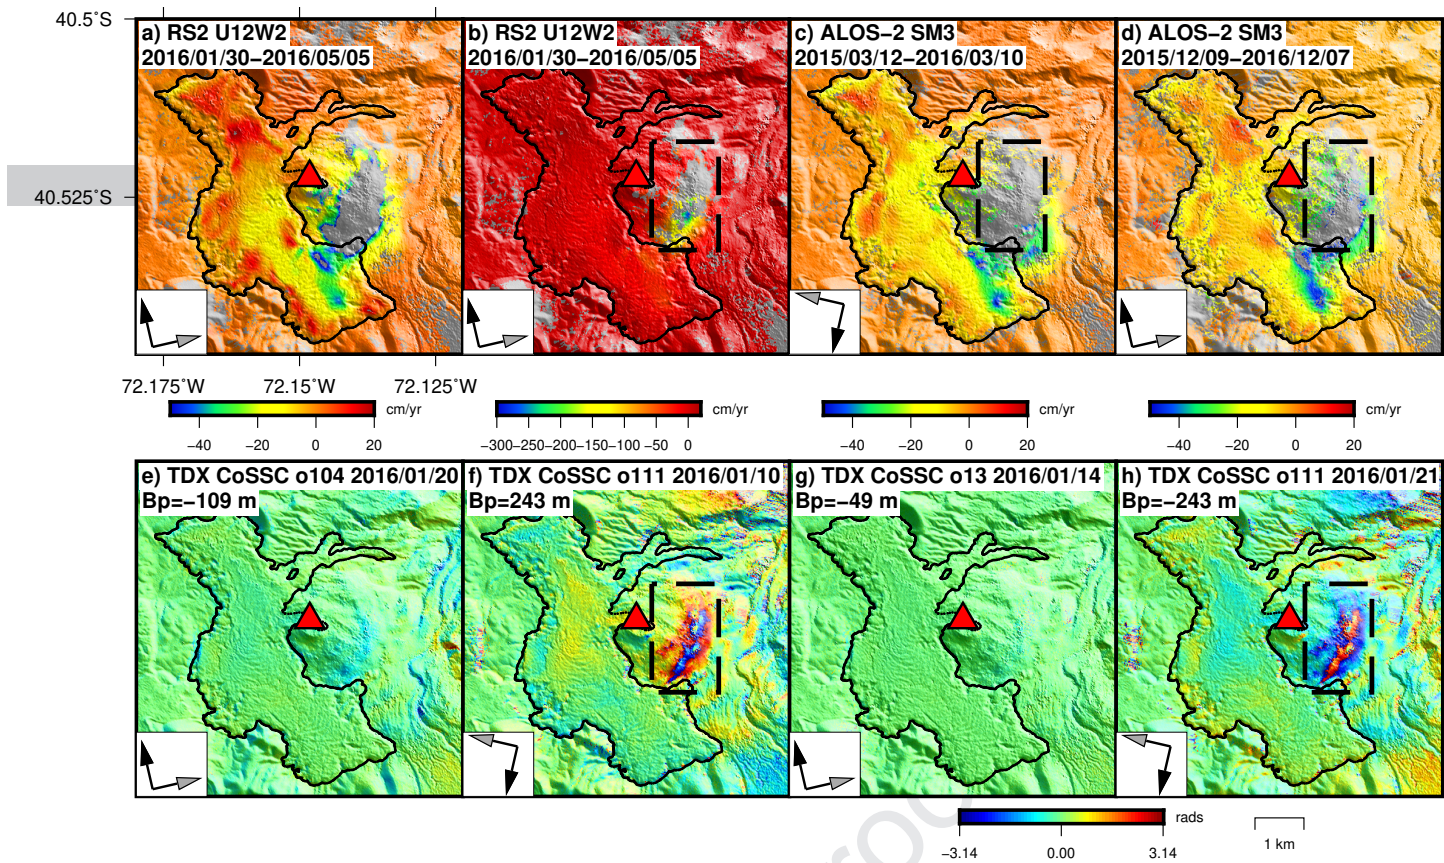

Figure 6: a-d) Mean ground velocity at the lava flow during a period with no deformation of magmatic origin. a-b) Mean ground velocity from a RADARSAT-2 Wide Ultra Fine 12 stack during February - May 2016. a) and b) show the same data but with different color scales to highlight deformation in the lava flow and in the laccolith respectively. The dashed black box shows the area of the laccolith. c-d) ALOS-2 SM3 interferograms that span one year showing mean ground velocity. e-h) TanDEM-X differential bistatic interferograms with the reference topographic phase removed with the 12m TanDEM-X DEM from 2011-2014. Here B_p is the perpendicular baseline. The dashed black box shows the area of the laccolith with a DEM error which propagates into subsidence with a high rate of 3 m/yr in the RS2 stack. The black and grey arrows show the satellite heading and LOS direction. The red triangle is the 2011 eruptive vent. The black thick line is the lava flow contour (*Bertin et al., 2015*).

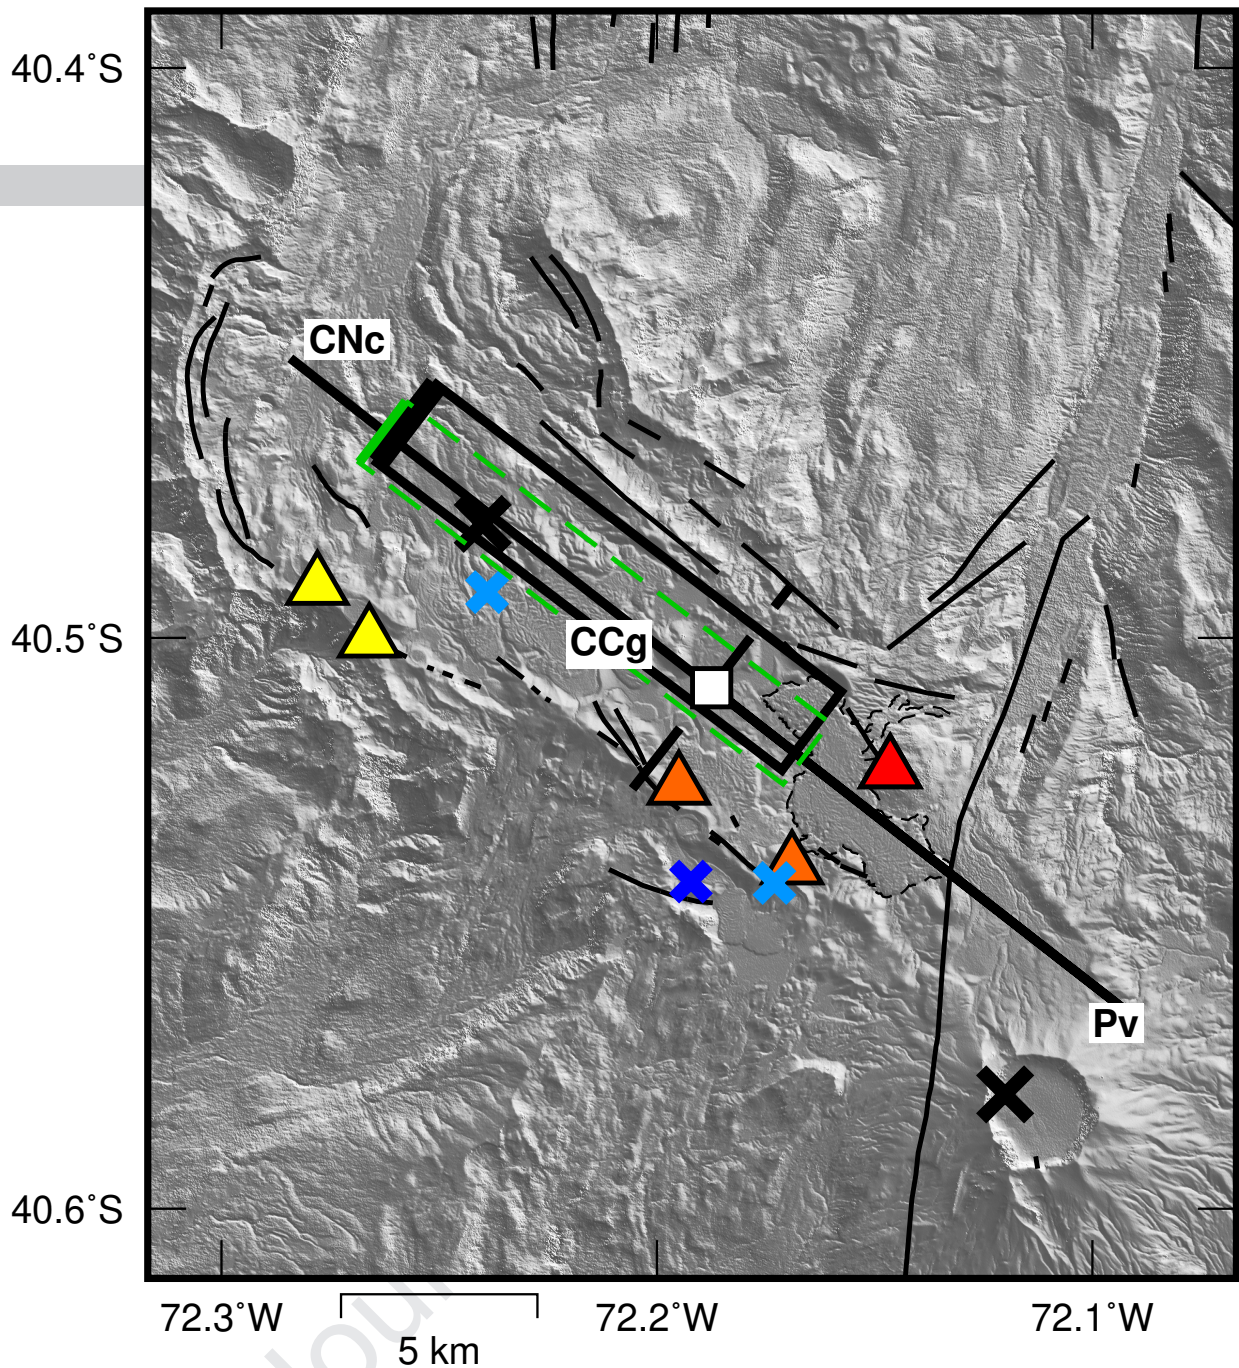

Figure 7: Compilation of deformation sources derived from InSAR inversions on top of TanDEM-X topography. The yellow, orange and red triangles are the 1921-1922, 1960 and 2011-2012 eruptive vents. The thin dashed outline is the 2011-2012 lava flow. The green rectangle is the 2003-2007 Okada source model (Figure 3, Figure S1), the light blue crosses are the 2007-2008 Mogi source model (Jay *et al.*, 2014), the blue cross is the 2008-2011 Mogi source model (Jay *et al.*, 2014), the black crosses are the Mogi sources for the first three days of the eruption (Jay *et al.*, 2014), the white square, thick black line and dashed black lines are the centroid, semi major- and semi-minor axes of the spheroid source model during the rest of the eruption (Figure 4, Delgado *et al.*, 2019), and the black square is the 2012-2017 Okada source model (Figure 5, Delgado *et al.*, 2018, 2016). The black lines are faults (Jay *et al.*, 2014)

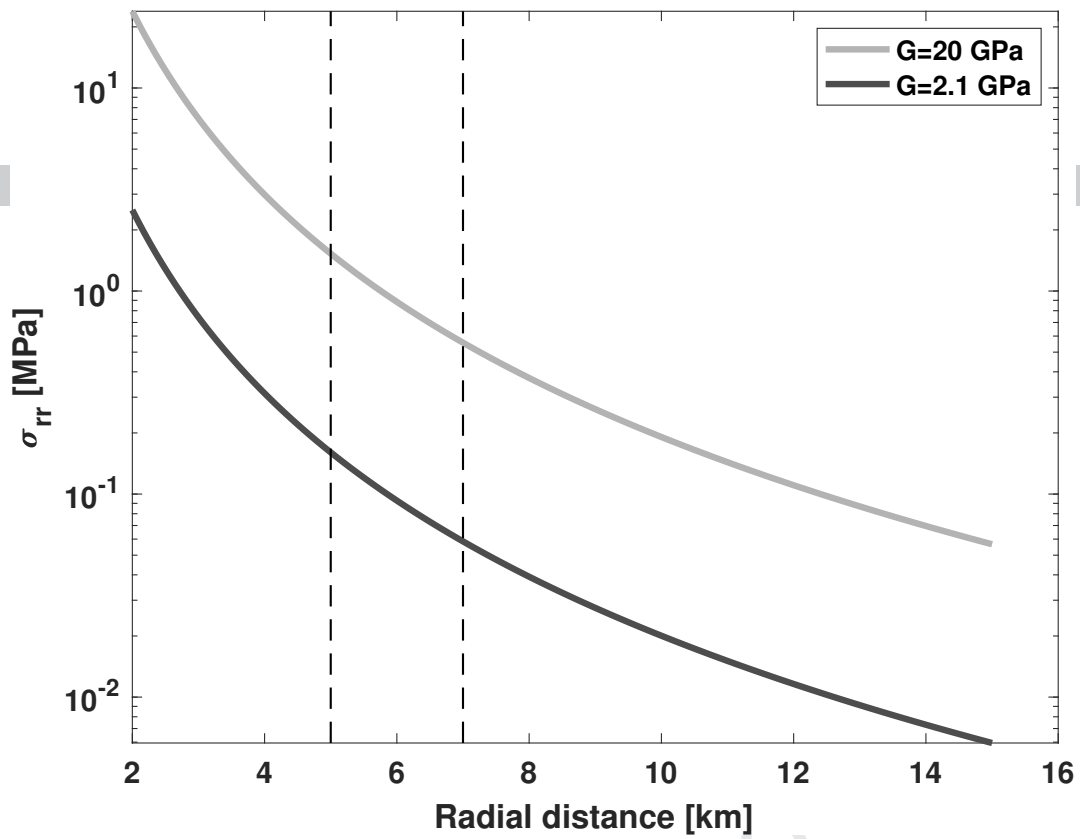

Figure 8: Radial stress (Equation 4) produced by a volume change of 0.03 km^3 in the deformation source active during the 2008-2011 episode of uplift as a function of radial distance and shear moduli ($G=2.1 \text{ MPa}$ from [Heap et al., 2020](#) and $G=20 \text{ MPa}$ from [Delgado et al., 2019](#)). Dashed lines show the range of distance between the 2008-2011 and the co-eruptive deformation sources. The figure shows that the volume change can increase the radial stress $0.08\text{-}2 \text{ MPa}$ on distances similar to those between the pre and co-eruptive deformation sources. See main text for details.

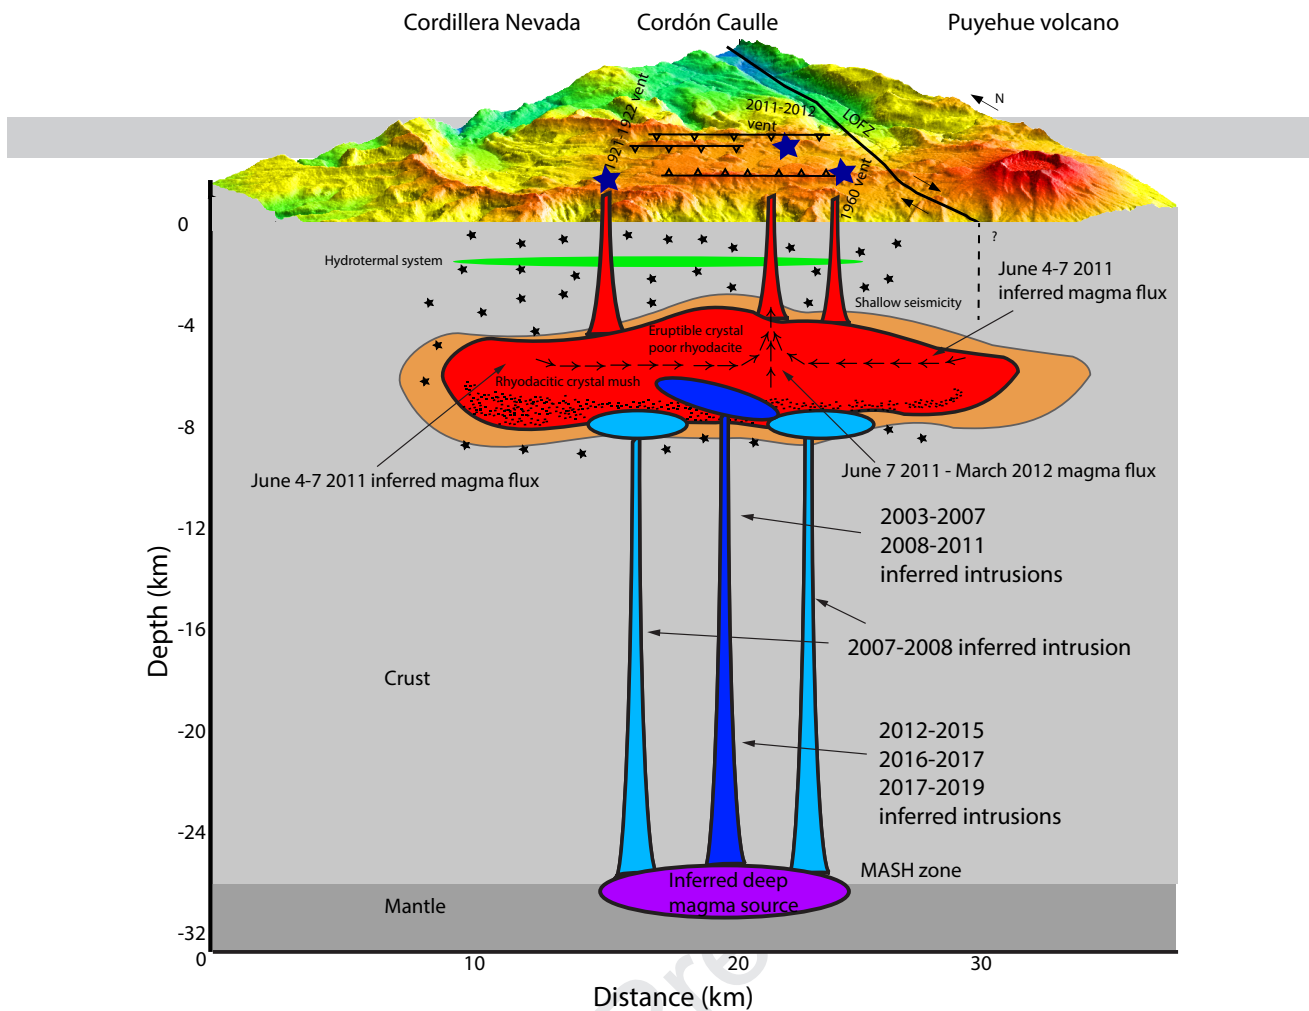

Figure 9: Cordón Caulle geological cross section (updated from [Delgado et al., 2016, 2018](#)) that summarizes the estimated deformation sources between 2003–2011, 2011–2012 and 2012–2019 derived from InSAR modeling and the inferred magma sources of the 1921–1922, 1960, and 2011–2012 eruptions from geobarometry ([Lara et al., 2006a](#); [Singer et al., 2008](#); [Castro et al., 2013](#); [Jay et al., 2014](#)). The red region is the hypothetical mush zone, likely surrounded by a viscoelastic shell (orange region). The storage region could also be a collection of discrete, connected reservoirs instead of a large, interconnected zone. Black points in the red regions show crystals that might have settled at the bottom of the reservoir, thus reducing the magma viscosity ([Castro et al., 2013](#)) and enhancing interstitial liquid extraction, a condition likely required to produce eruptible magma in a silicic magma chamber ([Bachmann and Bergantz, 2008](#); [Cooper, 2017](#)). The light blue regions show the inferred magma intrusion during 2007–2008, the blue region shows the inferred magma sources during 2003–2007, 2008–2011, 2012–2015, 2016–2017 and 2018–2019, and the green region is the hydrothermal system beneath the volcano ([Sepulveda et al., 2004](#); [Sepulveda et al., 2007](#)). Blue stars show the location of the historical eruptive vents, black stars are earthquakes beneath the volcano ([Delgado et al., 2016](#); [Wendt et al., 2017](#)), horizontal lines with open triangles show the graben bounding faults, and LOFZ is the Liquiñe-Ofqui regional fault zone that crosses the volcano ([Lara et al., 2006b](#)). MASH zone refers to a hypothetical zone of magma melting, assimilation, storage, and homogenization ([Hildreth and Moorbath, 1988](#)) that I infer to be the source of magmas (see rationale in [Jay et al., 2014](#)). The sketch shows that the source of the 1921–1922, 1960, and 2011–2012 eruptions is the same reservoir located beneath Cordillera Nevada, Cordón Caulle, and Puyehue volcanoes and where magma intruded during 2003–2007, 2007–2008, 2008–2011, 2012–2015, 2016–2017 and 2017–2019. InSAR data are interpreted to show that magma flowed from the Cordillera Nevada and Puyehue volcanoes towards the 2011–2012 eruptive event during the first three eruption days and then flowed from the same area where magma injection occurred afterwards. Note that the shape of the crystal mush is hypothetical because no geophysical imaging is available for the volcano.

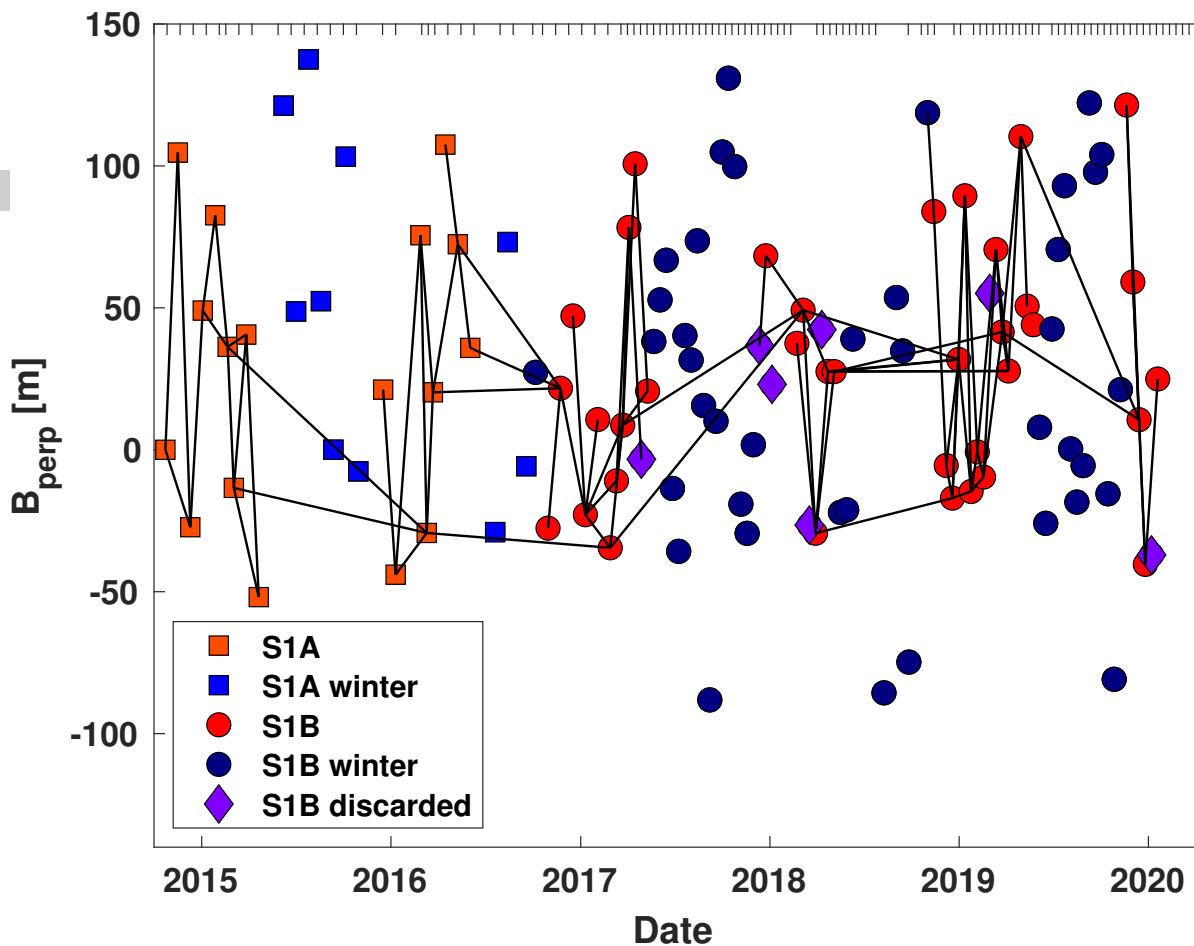

Figure 10: Perpendicular baseline (B_{perp}) plot for S1 SLCs from descending track 83. The time series for this track is in Figure 5g. Ticks on top of the figure show the date of the images, and clearly show the onset of 12 days acquisitions in February 2017 and several periods with data gaps. Blue squares and circles are SLCs acquired under winter conditions with snow on top of the volcano and purple circles are summer and early fall SLCs that result in interferograms with coherence loss either on top or on the vegetated flanks of the volcano. Black lines are interferograms used in the time series. The figure shows that despite the 12 day repeat period of the mission since February 2017, a significant amount of the small baseline interferograms are not useful due to their low coherence, even in the austral summer. Coherence loss was a severe problem during February 2017 - May 2018 but not as much during May 2018 - May 2019. Also, it is not straightforward to select summer to summer interferograms to ensure the connectivity of the InSAR network.

Table 1: Details of the processed SAR images for interferometry and DEM generation (*Jay et al., 2014; Bignami et al., 2014; Delgado et al., 2016, 2018, 2019; Wendt et al., 2017; Euillades et al., 2017*, this study). This table is not exhaustive and does not include all the existing SAR data. They do not include the data sets used for pixel tracking (Figure 4). Winter images (June 5 to October 15) have not been included in this compilation of data except for the co-eruptive ENVISAT data and for ALOS-2 ScanSAR. The columns show the satellite name, radar wavelength (λ), date range (year/month/day), whether the satellite is in an ascending (A) or descending (D) orbit, satellite path if available, average incidence angle (θ), radar mode, radar beam if available, number of synthetic aperture radar images (SAR) per track and the ground pixel size. SM is stripmap, FBD/FBS are the fine beam double/single polarization beams of ALOS-1 (14 and 28 MHz), SM3 is the stripmap beam of ALOS-2, HIMAGE is the SM mode of COSMO-SkyMED, TOPS is Terrain Observation by Progressive Scans, IW is Interferometric Wide Swath. The RADARSAT-2 beams for which data are available at Cordon Caulle are Wide Fine 2 (WF02), Wide Ultra Fine 12 and 16 (U12W2/U16W2) and Wide Multi Look Fine 23 (WLMF23). N/A refers to a information not available, like the RS2 and CSK path numbers.
