16

17 **Highlights**

- 18 • First Hauterivian acme of the *Crioceratites* belongs to *C. claveli* sp. nov. only
- 19 • *C. claveli* variation is under dimorphism, multipolar variation of order two and
20 heterochronies
- 21 • Multipolar variation is not under the strict Buckman's 1st Law in *C. claveli*
- 22 • New *C. claveli* (Sub-)Zones are introduced in replacement of *C. loryi* (Sub-)Zones
- 23 • *Crioceratites jurensis* is revised; its synonymy with *Davouxiceras nolani* is rejected

24

25 **Abstract**

26 Two acmes of the genus *Crioceratites* were recorded in the current *Crioceratites loryi* Zone
27 (lower Hauterivian) in the Lower Cretaceous series of south-eastern France (Vocontian
28 Basin), both in the classic section of the Cheiron ravine (Castellane area) and in the
29 Hauterivian GSSP area at La Charce. The revision of an abundant material allows us to define
30 *Crioceratites claveli* sp. nov. The first acme and the first part of the second acme correspond
31 to the range of *C. claveli* sp. nov. and not to *C. loryi* as previously admitted. The remaining of
32 the second acme is related to this latter species solely. The great abundance of *C. claveli* sp.
33 nov. in the lower interval Horizon allowed a detailed analysis of its variation around 3 factors:
34 (1) dimorphism; (2) multipolar variation of order two here characterized by an absence of
35 correlation between the ornamental and morphological shell parameters (non-covariant
36 factors); and (3) ontogenic heterochronies, which depend on the robustness of the
37 ornamentation only. On the other hand, the northern edge of the Provençal platform delivered
38 *C. jurensis* (revised here) from the top part of the *Acanthodiscus radiatus* Zone, which
39 reduces the gap with the older *Crioceratites* known in the uppermost Valanginian. Finally, the
40 study of the stratigraphic distribution of *C. claveli* sp. nov. and *C. loryi* leads to propose the
41 new *C. claveli* (Sub)Zone instead of the *C. loryi* (Sub)Zone. This proposal for the south-
42 eastern France may have extension potential for the Mediterranean Province of the
43 Mediterranean Caucasian Subrealm (Tethyan Realm).

44

45 **Keywords:** Heteromorphic ammonites; *Crioceratites*; Hauterivian; Intraspecific variability;
46 Biozonation; France.

47

48 1. Introduction

49

50 The heteromorphic ammonite group related to *Davouxiceras nolani* (Kilian, 1910) s.l. was
51 excluded from the *Crioceratites* Léveillé, 1837 s. str. and is now considered an
52 Emericiceratidae Vermeulen, 2004 (see Klein et al., 2007, p. 67). Consequently, the
53 appearance of the genus *Crioceratites* was recognized to coincide with that of *Crioceratites*
54 *loryi* Sarkar, 1955 (index species of the current *Crioceratites loryi* Zone, Reboulet et al.,
55 2018), that is to say widely beyond the base of the Hauterivian stage. This situation changed
56 with the discovery of ‘primitive *Crioceratites*’ at the top part of the Valanginian by Reboulet
57 (1996). However, the link between the Hauterivian and Valanginian *Crioceratites* was not
58 then evident due to the hiatus that remained throughout the thick *Acanthodiscus radiatus* Zone
59 (Reboulet, 1996, p. 277).

60 Research carried out in the south-east of France has shown that the stratigraphic distribution
61 of the *Crioceratites* in the current *C. loryi* Zone is organized around two acmes (Bulot, 1995,
62 tab. 16; Reboulet, 1996, fig. 23; and this work). However, when the stratigraphy is known
63 with sufficient precision, only the elements of the second occurrence have been cited and
64 figured in the literature (i.e. Thieuloy, 1972; Ropolo, 1995; Bulot, 1995, p. 93-94; Reboulet,
65 1996, p. 178, pl. 24, fig. 6): all these specimens correspond to the original representation of *C.*
66 *loryi* from Sarkar (1955) and to the very accurate description of this species by Thieuloy
67 (1972). It was therefore important to verify if the *Crioceratites* of the first acme indeed
68 correspond to the same species, and if it does not, to verify their relations with *C. loryi* and to
69 draw all the possible important biostratigraphic implications, *C. loryi* being a zonal index.

70 This research was carried out in the classic section of the Cheiron ravine (south-eastern
71 France, Alpes de Haute-Provence department, south of the Vocontian Basin), which, although
72 cited for a long time in the literature, has been the subject of only few studies and no precise
73 survey (Cotillon, 1971, fig. 3). The detailed bed-by-bed survey of the Hauterivian in the
74 Cheiron ravine was carried out for the first time by Vernet and Bert (Vernet, 2017,

75 unpublished Master thesis) as part of an internship at the Réserve naturelle nationale
76 géologique de Haute-Provence (RNNGHP). For the present work, this section was resampled
77 and yielded numerous ammonites including many *Crioceratites*. In the lower part of the
78 current *C. loryi* Zone (the first acme evoked previously; = new *Crioceratites claveli* Zone, this
79 work) all the *Crioceratites* belong to the same species (here *C. claveli* sp. nov.). The study
80 material of Reboulet (1996) from La Charce (the Hauterivian GSSP) was also reviewed, as
81 well as new elements from the complementary Pommerol section (Reboulet, 2015; Aguirre-
82 Urreta et al., 2019 – Drôme department, central part of the Vocontian Basin). The abundant
83 material from the first acme made it possible to perform a statistical analysis and identify the
84 variation of the sample studied on the basis of the intraspecific laws of variability recently
85 explored by Bert (2014a,b; 2019).

86 Additional research in the neritic domain of the Arc de Castellane (Provençal platform
87 boarder, southeastern France) did not allow finding the two occurrences of *Crioceratites* of
88 the current *C. loryi* Zone. However, several specimens of a related species [*Crioceratites*
89 *jurensis* (Nolan, 1894) – rehabilitated in this work] have been collected in the upper part of
90 the *A. radiatus* Zone, making it currently the oldest recognized *Crioceratites* s. str. species in
91 the Hauterivian.

92

93 **2. Geological setting**

94

95 The three main sections studied belong to the Vocontian Basin series (Paquier, 1900 – Fig. 1).
96 During the Early Cretaceous, the Vocontian Basin was located at a palaeolatitude of ~30°N in
97 a marginal marine position of the western Ligurian Tethys Ocean. This west-east oriented
98 basin corresponded to a deep (a few hundred meters) depositional environment (pelagic
99 series), and included the Diois-Baronnies region and the tectonic arc of Digne-Castellane in

100 the west and east parts, respectively (Ferry, 2017). It was surrounded by slopes (transitional
101 domain, hemiplegic series) and platforms (neritic series; Vercors, Vivarais and Provence
102 regions). The dilated/expanded Hauterivian sections of the Vocontian Basin s.l. provide good
103 conditions to follow the succession and evolution of ammonite faunas with great precision.

104
105 The Cheiron ravine (CHE – Castellane; Cotillon, 1971) provided the main part of the fossils
106 studied. Although located in the pelagic domain of the southern part of the Vocontian Basin
107 (the Eastern Subalpine Basin in the sense of Ferry, 2017), this section is very close to the
108 hemipelagic domain from which it receives some influences (Fig. 1). From a structural point
109 of view, this section belongs to the southern subalpine chains of the Arc de Castellane, which
110 are the outermost units of the Alpine Arc. The La Charce (LCH – Hauterivian GSSP;
111 Reboulet et al., 1992; Reboulet, 1996; Reboulet and Atrops, 1999; Mutterlose et al., 2020)
112 and Pommerol sections (POM – Drôme department; Reboulet, 2015; Aguirre-Urreta et al.,
113 2019) are located in the western part of the Vocontian Basin (the Vocontian through in the
114 sense of Ferry, 2017), in the pelagic domain (Fig. 1).

115 The successions of the three sections studied (CHE, LCH, POM) are characterized by
116 marlstone-limestone alternations, which have been interpreted as the result of cycles in the
117 production of calcareous nannoplankton caused by climatic fluctuations in the Milankovitch
118 frequency band (Cotillon et al., 1980; Giraud et al., 1995). Alternatively, Reboulet et al.
119 (2003) have proposed a model of cyclic export of carbonate mud from shallow platform
120 environments towards the basin for the Valanginian successions of the Vocontian Basin.
121 Occasionally, synsedimentary slumps occurred in the basin.

122 Some sections of the Provençal platform boarder (Arc de Castellane) were sampled for the
123 present work (Rougou and La Palud-sur-Verdon area in the Alpes de haute-Provence
124 department: CAR, PV2 – Cotillon, 1971; Bulot et al., 1995; Reboulet, 1996 – and Bargème

125 area in the Var department: COU1; Fig. 1). These sections are characterized by neritic
126 deposits with often reduced and sometimes discontinuous sedimentation, in particular in the
127 lower Hauterivian.

128

129 **3. Material and methods**

130

131 **Stratigraphy.** The Crioceratitidae are relatively rare in the upper Valanginian and more
132 abundant in the lower Hauterivian substage (Reboulet, 1996, figs. 22-23). For this
133 stratigraphic interval, numerous works dealing with paleontology and biostratigraphy were
134 made during the last four decades; they allowed to improve the zonal scheme of the upper
135 Valanginian–lower Hauterivian of the south-east France basin (Thieuloy, 1977; Reboulet et
136 al., 1992; Bulot et al., 1993, 1995; Thieuloy and Bulot, 1993; Bulot, 1995; Bulot and
137 Thieuloy, 1995; Reboulet, 1996, 2015; Reboulet and Atrops, 1999). These studies provide a
138 sound base for the standard Mediterranean ammonite scale accepted by the Kilian Group
139 (Hoedemaeker et al., 2003; Reboulet et al., 2006; 2009; 2011; 2014; 2018); this Lower
140 Cretaceous standard zonation is applied here.

141 The terminologies used in this paper (biostratigraphy and chronostratigraphy versus
142 geochronology) respect the standards of the International Commission on Stratigraphy
143 (Salvador, 1994).

144 **Material.** This study focuses on the discovery of new bed-by-bed sampled material of the
145 genus *Crioceratites* in the lower Hauterivian. The main part of this material (122 specimens)
146 comes from the sections CHE (88 specimens), LCH (26 specimens) and POM (8 specimens)
147 and belongs to the species *C. claveli* sp. nov. Five other specimens of the little-known species
148 *C. jurensis* were collected in the sections CAR, PV2 and COU1.

149 All the sections studied in the Alpes de Haute-Provence and Var departments belong to the
150 protected perimeter of the ‘Réserve naturelle nationale géologique de Haute-Provence’
151 (RNNGHP), managed by the Departmental Council of the Alpes de Haute-Provence on behalf
152 of the French State. The section LCH is the GSSP of the Hauterivian stage; this site is
153 protected as an ‘Espace naturel sensible’ (Mutterlose et al., 2020).

154 **Repositories.** The material from LCH and POM sections is stored in the palaeontological
155 collections of the Claude Bernard University of Lyon (France, collections of Reboulet, and
156 Reboulet and Noclin). The material collected in the CHE section (Bert’s collection) is curated
157 by the RNNGHP. Some interesting specimens were added to the study albeit they are in a
158 private collection (L. Canut): they are a minority, and of course they are never used as type
159 specimens; the curating of these specimens is monitored by the RNNGHP.

160 Collections acronyms: MHNG=Museum of Natural history of Geneva (Switzerland);
161 FSL=Faculté des Sciences de Lyon; RNNGHP=Réserve naturelle nationale géologique de
162 Haute-Provence; DBT=D. Bert; LCT=L. Canut.

163 **Measurements.** The ammonoid fauna is relatively well preserved, but the fragmentation of
164 specimens can be frequent in some beds. Dissolution of the ammonoid shells is the norm and
165 specimens are preserved as internal calcareous moulds. The compaction of ammonites
166 sampled in the pelagic part of the Vocontian Basin is relatively important, particularly for the
167 phragmocone part of the shell. Consequently, some characteristics such as the thickness of
168 whorl section cannot be observed and compared most of the time. The suture lines are not
169 always well preserved (especially in pelagic deposits), however their systematic presence
170 indicates the beginning of the body chamber. The abbreviations used for the measurements
171 (mm) are: D=diameter; H=whorl height; W=whorl thickness; U=umbilical diameter; h=spiral
172 hiatus; Nt/2=number of tuberculate (main) ribs per half whorl; Ni/2=number of smooth ribs
173 (intercalatories) per half whorl. When measurements were taken at multiple diameters on the

174 same specimen, the angle alpha between each successive measurement has been shown in the
175 tables.

176 **Analysis.** In the present work, the sample of *Crioceratites claveli* sp. nov. from the basis of its
177 stratigraphic range (the first acme previously evoked, here the *C. claveli* lower interval
178 Horizon) is the only sufficiently large and homogeneously preserved to be statistically
179 analyzed; this would also allows avoiding time-averaging as much as possible. Statistical
180 analyses and tests were carried out using PAST, version 3 (Hammer et al., 2001). The method
181 used has already been described by Bersac and Bert (2012) and Bert (2014a), and will not be
182 given in detail here again. A digital matrix was made from different measures of the
183 quantifiable characters (continuous and discrete variables) and ratios of some of them.
184 Continuous parameters tested were D, H, U and h. The specimens often have a side embedded
185 in the rock and most are compressed post mortem, so the variables associated with W were
186 not tested due to lack of effective (significance level not reached). This is also the case for the
187 diameters of the ontogenic stages, which could not be integrated into the statistical analysis
188 for the same reasons, but they were taken into account in the descriptive analysis.
189 Conventional ratio H/D (relative height), U/D (relative umbilicus) and U/H were calculated.
190 The discrete variables tested are Nt/2 and Ni/2. Significance level of probability tests was set
191 at $p=0.05$. Univariate and bivariate analyses were employed to visualize and test the
192 homogeneity of the sample, the possible variation through ontogeny, and correlations between
193 parameters two by two. Multivariate analysis allows (1) investigation of the contribution of
194 each variable relative to the total morphospace occupation of the sample, (2) investigation of
195 the relationships between variables, and (3) to test groups recognized in the descriptive
196 analysis (i.e. dimorphs) considering all the variables simultaneously.

197

198 **4. Description of the sections**

199

200 **4.1. The Cheiron ravine**

201

202 The palaeontological site of the Cheiron ravine has been known very probably since the
203 beginning of the 19th century and has been visited for a very long time by local
204 paleontologists (Astier, Jaubert, Duval-Jouve, Emeric, Audoul, Puzos, etc.). This long
205 frequentation allowed the introduction of at least 30 species of ammonites from the Lower
206 Cretaceous series, including zonal indexes [for example *Plesiospidiscus ligatus* (d'Orbigny,
207 1841)], which make this site one of the most important for the Hauterivian stage in the south-
208 east of France. Despite this historical past, the only study of this locality was from Cotillon
209 (1971) who gave an imprecise synthetic geological section.

210

211 The Hauterivian lithology of the Cheiron ravine is composed of a relatively regular alternation
212 of marlstone and limestone beds over 205 m thick, more compact at the top of the series. Only
213 a limited slump area disturbs the Hauterivian succession in the lower part of the *Subsaynella*
214 *sayni* Zone and causes an about 5 m thick invisibility. The beds and interbeds are thick in the
215 *Acanthodiscus radiatus* Zone, and then they tend to thin out in the current *Crioceratites loryi*
216 Zone (Fig. 2; = new *C. claveli* Zone, this work). The top part of the current *C. loryi* Subzone
217 (= new *C. claveli* Subzone, this work) is formed by a small marly ledge between the beds
218 194-198. A second marly ledge is located at the limit between the *Olcostephanus jeannoti*
219 Subzone and the *Lyticoceras nodosoplicatum* Zone (beds 206-214). In the current *C. loryi*
220 Zone (= new *C. claveli* Zone, this work), three beds are exceptionally rich in fossils: bed 179
221 at the base of the zone (first acme of the genus *Crioceratites*), the very marly bed 195 (10 cm
222 thick), which constitutes a Konzentrat-Lagerstätte type deposit (bioclastic accumulation), and
223 bed 197 just below the *O. jeannoti* Subzone. Beds 195-197 form the second acme of the

224 genus. In bed 195, the fossils are very compressed and fragile structures such as spines are
225 often kept in place; we also note the presence of many aptychi and very scattered grains of
226 glaucony. The fauna is mainly made up of *C. claveli* sp. nov. in beds 179 and 195, which
227 contain the First Occurrence (FO) and Last Occurrence (LO) of the species respectively, and
228 by *C. loryi* in beds 196-197. In the other beds of the current *C. loryi* Subzone (= new *C.*
229 *claveli* Subzone, this work), *Neolissoceras grasianum* (d'Orbigny, 1841) is often the more
230 abundant. The first *Crioceratites curnieri* Ropolo, 1992 have been observed to date in bed
231 201.

232

233 **4.2. The La Charce-Pommerol sections**

234

235 A detailed lithology of the upper Valanginian-lower Hauterivian at La Charce was made
236 previously by Reboulet et al. (1992), Bulot et al. (1993; 1995), Bulot (1995), Reboulet (1996;
237 2015) and Reboulet and Atrops (1999). In the upper Valanginian, the *Saynoceras verrucosum*
238 Zone is a marly-dominated interval; the relative abundance of carbonate in the marlstone-
239 limestone succession increases gradually during the *Neocomites peregrinus* and
240 *Criosarasinella furcillata* zones. Carbonate-rich marlstone-limestone alternations
241 predominates the lower Hauterivian beds (*Acanthodiscus radiatus*, *Crioceratites loryi* and
242 *Lyticoceras nodosoplicatum* zones).

243 In the La Charce section, the continuity of the marlstones-limestone alternation deposits is
244 interrupted by two slumps in the lower Hauterivian observed at the top part of the *A. radiatus*
245 Zone and across the boundary between the current *C. loryi* and *L. nodosoplicatum* zones.
246 However, the stratigraphic intervals equivalent to these two slumps were correlated to the
247 nearby Pommerol section characterized by undisturbed marlstone-limestone alternations
248 (Reboulet, 2015; Aguirre-Urreta et al., 2019). These authors provided additional data allowing

249 to complete more precisely the lower Hauterivian ammonoid distribution previously
250 established for the La Charce section.

251

252 **5. Descriptive palaeontology**

253

254 Class: Cephalopoda Cuvier, 1798

255 Order: Ammonoidea Agassiz, 1846

256 Suborder: Ammonitina Hyatt, 1889

257 Superfamily: Perisphinctoidea Steinmann, 1890

258 Family: Crioceratitidae Gill, 1871

259 Genus *Crioceratites* Léveillé, 1837

260

261 **Type species.** *Crioceratites duvalii* Léveillé, 1837.

262

263 ***Crioceratites jurensis* (Nolan, 1894)**

264 Figs. 3-5

265 **Synonymy.**

266 *vm* 1861 *Ancyloceras duvalii*, 'type 1'; Pictet and Campiche: p. 37-39, p. 49; pl. 47bis, fig. 1a-
267 b.

268 1894 *Crioceras picteti* var. *jurensis* nov.; Nolan: p. 192.

269 1910 *Crioceras jurense*; Kilian: p. 270.

270 ?1936 *Crioceratites* sp. juv. gr. *jurensis*; Breistroffer: p. 145.

271 *non* 1967 *Crioceratites jurensis*; Dimitrova: p. 44; pl. XVIII, fig. 1.

272 **Holotype by monotypy.** Specimen MHNG GEPI 16787 (Fig. 3) of the Pictet's collection,
273 curated in the Museum of Natural history of Geneva (Switzerland).

274 **Type locality.** The Ravin Saint-Martin area, near Escragnoles (Alpes-Maritimes,
275 southeastern France).

276 **Type horizon.** Unspecified in the original work of Pictet and Campiche (1861), but the type
277 specimen is said by these authors (p. 39) to come from a bed that yielded also *Acanthodiscus*
278 *radiatus* (Bruguière, 1789), *Oosterella cultrata* (d'Orbigny, 1841), *Neolissoceras grasianum*
279 (d'Orbigny, 1841) and *Lyticoceras cryptoceras* (d'Orbigny, 1840). In the type locality, the
280 Hauterivian basis is condensed in a fossiliferous level with numerous *Acanthodiscus* Uhlig,
281 1905 and *Leopoldia* Mayer-Eymar, 1887 (Kilian and Zürcher, 1896), and it is highly probable
282 that this level has also delivered the type specimen of *Crioceratites jurensis*.

283 **Geographic distribution.** Southeastern France (neritic domain of the 'Arc de Castellane'),
284 Switzerland ('Hauterive marlstones' in Pictet and Campiche, 1861, p. 49).

285 **Stratigraphic distribution.** New specimens were collected (LC and DB) at La Palud-sur-
286 Verdon and Carajuan (Rougou, south-east of France) together with numerous *Leopoldia*
287 above the beds rich in *Acanthodiscus radiatus* (Carajuan, bed 88 in Bulot et al., 1995, fig. 7),
288 just below the gap of most of the current *C. loryi* Zone (= new *C. claveli* Zone, this work).
289 This species is therefore restricted to the upper part of the *A. radiatus* Zone, without further
290 details in the current state of knowledge (= *Leopoldia buxtorfi* Horizon of Bulot, 1995).

291 **Material studied (N=6).** Six specimens, all from the platform boarder of the 'Arc de
292 Castellane' (South-East of France), including the cast of the holotype provided by Lionel
293 Cavin (curator of the Museum of Natural history of Geneva). Two specimens (DBT.BC47 and
294 DBT.BC48) are from the bed 88 of the Carajuan section (Rougou, Alpes de Haute-Provence
295 department – see Bulot et al., 1995, fig. 7). Two specimens are from the same equivalent level
296 in an unpublished section near La Palud-sur-Verdon (Alpes de Haute-Provence, DBT.BG31
297 and LCT.7Z). The last specimen is from the locality of Bargème (unpublished section – Var

298 department, DBT.BC49), in a condensed bed assigned to the *A. radiatus* Zone with
299 ferruginous ooliths.

300 **Description.** The shell is cryptoconic, rather weakly uncoiled, with a spiral hiatus which
301 increases regularly with growth. The whorl section is relatively depressed, nearly sub-circular,
302 more compressed in the inner whorls, but this is increased by the greater post mortem
303 compression at this level. Taking into account the length of the adult body chamber (more
304 than 1/3 of a whorl), the reconstructed size reached 120 mm (DBT.BC47 – Fig. 4) to 165 mm
305 in diameter (LCT.7Z – Fig. 5; DBT.BG31). The ontogenetic sequence is as follows (note that
306 the ornamentation of the ventral area is known on the studied specimens only from the
307 ontogenetic stage 4):

308 - Stage 1 ‘initial trituberculate’ up to about 15-20 mm in diameter: the ornamentation
309 is differentiated with main trituberculate ribs bearing large nodular tubercles; the lateral
310 tubercle is located towards the mid-flank. The intercalary ribs are smooth and few in number.

311 - Stage 2 ‘with nodular periventral tubercles’ up to D=50-55 mm: the ornamentation is
312 weakly differentiated, with main bituberculate ribs bearing tubercles near the umbilicus and
313 on the periventral area. The latter tubercle is distinctly nodular. Fasciculations (several sickle-
314 ribs that start from the same periumbilical tubercle) are exceptional and limited to a very few
315 ribs only. The periventral tubercle is thorny compared to the periumbilical one; it is well
316 marked and lengthened in the longitudinal direction. The ribs are slightly tipped forward in
317 the middle of the flanks, which gives them a flexuous appearance.

318 - Stage 3 ‘with spiny periventral tubercles’, up to D=110-130 mm: the ribs are better
319 differentiated with the total loss of the fasciculation and the acquisition of true trituberculate
320 main ribs generally separated by 5-6 smooth interribs. The tubercles, however, remain
321 inconspicuous on the material studied; the periventral tubercle loses its nodular appearance
322 characteristic of the previous stage.

323 - Stage 4 'adult', up to D=150-165 mm. The ornamentation becomes more irregular
324 than in the previous stage; the intercalary ribs are reinforced, spaced out, and their distinction
325 from the main ribs becomes sometimes less obvious. The main ribs (and sometimes the
326 intercalaries when they are strong) remain trituberculate with a lateral tubercle. They can be
327 grouped into doublets separated by a weak constriction with a flat bottom. The bifurcations on
328 the top of the flanks are rare. All the ribs cross the ventral area, and the main ones substantially
329 strengthen. The body chamber (probably adult) starts between 90 and 110 mm in diameter.

330 The suture lines are very indented, of the ELUI type according to the terminology used by
331 Wiedmann (1966), with a well marked and deep lateral lobe L. It is trifold and each of the three
332 branches is narrow and well developed. The umbilical lobe U is also trifold, shallower than L
333 and more stocky. The siphonal lobe E is shallower than L; it is bifid with elongated and
334 narrow terminal branches. The following formula is respected: $L > E > U$.

335 **Discussion.** Dimorphism is not yet known in *C. jurensis*, probably due to a lack of specimens.
336 By comparison with the other related species for which the dimorphic pairs have been
337 recognised (*C. loryi* and *C. claveli* sp. nov.), it seems that the specimens described herein all
338 belong to the macroconch dimorph.

339 The specimen from the Pictet's collection, shown by Pictet and Campiche (1861, pl. 47 bis,
340 fig. 1), and which was later used as type for *C. jurensis* by Nolan (1894) was never refigured.
341 It could be found by Lionel Cavin in the collections of the Museum of Geneva and the
342 synonymy with *Davouxiceras nolani* proposed by Sarkar (1955), and followed by Klein et al.
343 (2007), is rejected here. Actually, Pictet and Campiche (1861, p. 38-39, 49) themselves
344 recognized the differences between this specimen (their fig. 1) and the one in their figure 2
345 (Pictet and Campiche, 1861, pl. 47bis), which the latter would later become the type of *D.*
346 *nolani*. The two species are clearly not of the same group, *C. jurensis* belonging to the genus
347 *Crioceratites* s.str.

348

349 Thus, *Crioceratites jurensis* is also very different from *Davouxiceras coniferus* (Busnardo et
350 al., 2003), although they can be found in the same levels. This latter species has a much more
351 open coiling. New specimens (LC, DB and Poupon collections) show that it could reach a
352 large to very large adult size, between 360 mm and up to probably around 500 mm. We do not
353 recognize in *D. coniferus* the ontogenic stages described in *C. jurensis*: in the former, the
354 trituberculation is constant with ribs always differentiated into very strong main ribs and
355 smooth intercalaries, which seem to become scarce or even disappear on the adult body
356 chamber. This is the morphology usually accepted by authors as characteristic of the group of
357 '*Davouxiceras nolani*' sensu lato (Klein et al., 2007). The type specimen of *D. coniferus* and
358 the specimen studied by Reboulet (1996; = *Crioceratites* n. sp. 1, pl. 24, fig. 7), reported to
359 this species by Busnardo et al. (2003), are assigned to the lowermost part of the Hauterivian
360 (*A. radiatus* Zone). Since then, Vašíček (2005) has reported *D. coniferus* in the upper
361 Valanginian (*Criosarasinella furcillata* Zone and Subzone).

362

363 *C. jurensis* is closer to *C. loryi* (Fig. 6), with which it shares the general morphology of the
364 shell, and with which it has many affinities. The adult size of *C. jurensis* appears to be slightly
365 smaller than that of *C. loryi* (150-165 mm vs. 180 mm). The initial trituberculate stage is
366 common to the both species, but it is distinctly shorter in *C. loryi* (5-7 mm vs. 15-20 mm).
367 Stage 2 is slightly longer in *C. jurensis* (50-55 mm vs. 40 mm), but the characteristic
368 fasciculations of *C. loryi* are almost absent or only limited to a few ribs. *C. jurensis* stage 3 is
369 also longer (110-130 mm vs. 90 mm), with the presence of systematic trituberculate main ribs,
370 which is not the case in *C. loryi* where the ribs are bituberculate. Finally, the adult stages 4 of
371 the both species are quite similar, but the ribs are still trituberculate in *C. jurensis*. Note that
372 this aspect is less evident in the type of *C. jurensis* due to wear of the specimen.

373

374 *C. jurensis* has a more regular coiling than *C. curnieri*, which varies between crioconic to
375 subaspinoceratic poles. In stages 3 and 4, *C. jurensis* shows fairly constant trituberculate ribs
376 pattern that is never the case with *C. curnieri*, which is bi- or even monotuberculate. The
377 ornamentation of *C. jurensis* is markedly less regular than that of *C. curnieri*. Finally, *C.*
378 *curnieri* is more recent, as it appears in the *O. jeannoti* Subzone and becomes more abundant
379 in the *L. nodosoplicatum* Zone (Ropolo, 1992; Bulot, 1995; Reboulet, 2015; Aguirre-Urreta et
380 al., 2019).

381

382 Some specimens of *Crioceratites heterocostatus* Mandov, 1976 could have an aspinoceratic
383 coiling of the adult body chamber (see Reboulet, 1996, pl. 24, fig. 1), which is never the case
384 in *C. jurensis*. *C. heterocostatus* is also smaller with a diameter up to 100 mm (vs. at least
385 150-165 mm). We recognize almost the same succession of ontogenic stages (in particular
386 stages 1 and 2, which are quite similar), with the exception of stage 3 ‘with spiny periventral
387 tubercles’, absent in *C. heterocostatus*, which de facto prolongs stage 2 up to 60-70 mm in
388 diameter (vs. 50-55 mm in *C. jurensis*). There are still other differences between these two
389 species: the strongly trituberculate juvenile stage 1 is shorter in *C. jurensis* (15-20 mm vs. 20-
390 30 mm); in adult stage 4, *C. heterocostatus* is bituberculate while *C. jurensis* is trituberculate;
391 rib bifurcations on the upper flanks are rarer in *C. jurensis* (stage 4). On the other hand, the
392 duplication of ribs on the adult body chamber is present in the both species, as in *C. loryi*.
393 Following Vašíček (2005, p. 252, see also Klein et al., 2007, p. 44, note 31) and Company (in
394 Klein et al., 2007, p. 40, note 30), we consider that *Crioceratites primitivus* Reboulet, 1996 is
395 a junior synonym of *C. heterocostatus* Mandov 1976. This latter is reported from the
396 Menhegini-Cryptoceras Zone of the Western Balkanids, which places it in the lower
397 Hauterivian for Mandov (1976), while it would be more likely uppermost Valanginian for

398 Thieuloy (1977, p. 127). This older age, confirmed by Vašíček (1995, p. 171), reinforces the
399 hypothesis of synonymy between the two species, with *C. heterocostatus* taking precedence.

400

401 ***Crioceratites claveli* sp. nov.**

402 Figs. 7-12

403 **Synonymy.**

404 1997 *Crioceratites* sp.; Faraoni et al.: p. 69, pl. 7, fig. 17.

405 **Derivation of name.** This species is dedicated to the memory of our French paleontologist
406 colleague Bernard Clavel (1938-2018†).

407 **Zoobank Record.** LSID urn:lsid:zoobank.org:act:790B5346-0463-44D4-961B-
408 B111EA4D17AA.

409 **Holotype.** Specimen DBT.BB48 (Fig. 7a-b) of the Bert's collection, curated by the
410 RNNGHP.

411 **Type locality.** The Cheiron ravine, near Castellane, section CHE (Alpes de Haute-Provence,
412 southeastern France).

413 **Type horizon.** The bed CHE/179 of the type locality, at the very basis of the *Crioceratites*
414 *loryi* Zone in its current acceptance (= new *C. claveli* Zone, this work).

415 **Geographic distribution.** The species is currently known in south-east of France (Alpes de
416 Haute-Provence and Drôme departments) and in Italy (Marche Apennines).

417 **Stratigraphic distribution.** The lower stratigraphic limit of *C. claveli* sp. nov. is the bed with
418 the first acme of the genus *Crioceratites* at the lowermost part of the current *C. loryi* Zone (=
419 new *C. claveli* Zone, this work) and its upper limit is in the second acme of the genus, just
420 below the appearance of *C. loryi* at the top part of the current *C. loryi* Subzone (= new *C.*
421 *claveli* Zone, this work and see also Reboulet, 1996, fig. 23). In the Cheiron ravine, this

422 distribution includes the beds CHE/179-195 and the beds LCH/219-229 in the La Charce
423 section.

424 **Diagnosis.** Dimorphic crioconic shell with weak spiral hiatus in the inner whorls. Four stages
425 during ontogeny: stage 1 'initial trituberculate' up to D=9 mm; stage 2 with 'nodular
426 periventral tubercles' up to approximately D=20-35 mm for the microconchs and D=45-50
427 mm for the macroconchs (differentiated ribs; main ribs bituberculate, exceptionally
428 trituberculate; sometimes fasciculation with 2-3 ribs); stage 3 'with spiny periventral
429 tubercles', up to D=56-70 mm in microconchs and D=95-115 mm in macroconchs, with less
430 regular and flexuous ornamentation than in the previous stage (irregular appearance of
431 trituberculation – lateral tubercle); stage 4 'adult', up to D=78-90 mm for the microconchs
432 and D=135-145 mm, even 165 mm, for the macroconchs, with well individualized
433 trituberculate main ribs and frequent duplicating of the main ribs. Stages 2-4 show long and
434 highly developed spines on the periumbilical, lateral and periventral tubercles.

435 **Material studied (N=124).** Ninety specimens are from the Cheiron ravine (CHE) near
436 Castellane (Alpes de Haute-Provence, France): 32 are from bed CHE/179, which are
437 numbered DBT.BB48, DBT.BB49, DBT.BB51 to DBT.BB76 and DBT.BB92 to DBT.BB94
438 (DBT.BB55 bears two specimens), 3 are from bed CHE/180, which are numbered
439 DBT.BB71, DBT.BB74 and DBT.BB95, 1 is from bed 194 (DBT.BG49), and 54 are from
440 bed 195 (DBT.BB79, DBT.BG49 to DBT.BG64 and DBT.BG67 to DBT.BG88, some
441 numbers having several specimens). In addition some unnumbered fragmentary specimens
442 where collected in beds 189, 190, 193 and 195 (Fig. 2). Height specimens are from Pommerol
443 (POM), all from bed POM/219. They are temporarily numbered POM 219-2, 3, 5, 7, 8, 12, 20
444 and 23. Twenty-six specimens are from La Charce (LCH). They are numbered FSL 487738
445 (LCH/226), FSL 487736 a-j (LCH/220), FSL 487733 a-l (LCH/219), FSL 487739
446 (LCH/225), FSL 487738 (LCH/226) and FSL 487743 a-b (LCH/229).

447 **Description.** The shell is heteromorphic, of the crioconic type. The spiral hiatus is weak in
448 the inner whorls, but this parameter can be parasitized by the significant post mortem crushing
449 of the specimens in the phragmocone, and it tends to grow significantly in the adult body
450 chamber (Fig. 8). Dimorphism was recognized by the adult size and the diameter reached by
451 the various ontogenic stages. There are 4 stages during ontogenesis:

452 - Stage 1 'initial trituberculate' up to $D=9$ mm on average, with differentiated ribs, the
453 main ones having large lateral tubercles at mid-flanks (Fig. 7f). The ribs are simple, straight
454 or slightly retroverted. The section of the whorl is more rounded than on the rest of the shell.

455 - Stage 2 'with nodular periventral tubercles' up to approximately $D=20-35$ mm for
456 microconchs and $D=45-50$ mm for macroconchs: the ornamentation is quite irregular from
457 one specimen to another. The ribs are differentiated; the main ribs are bituberculate,
458 exceptionally trituberculate (lateral tubercle very discreet when present – FSL 487736f).
459 There is some variation in the strength and density of the ornamental pattern, and the more
460 slender specimens have markedly less marked rib differentiation with very inconspicuous
461 tubercles. Most often, fasciculation (several ribs starting from the same periumbilical
462 tubercle) concerns only a small number of ribs (2-3); it is usually rare but more frequent in
463 slender specimens. The periumbilical tubercle is thorny, slightly elongated in the direction of
464 the rib which supports it. The periventral tubercle is quite nodular and sometimes groups
465 together several ribs by fibulation (two lateral ribs which meet at the top of the flank – Fig.
466 9b-c). When the preservation conditions allow it (as for example in the CHE/195 bed), it is
467 possible to observe that all the tubercles (periumbilical, lateral when present and periventral)
468 are extended by a triangular elongated spine, more or less thin, even for poorly developed
469 tubercles (Fig 7b and 10 shows example of the lateral and periventral spines respectively; note
470 that the periumbilical and lateral spines are unfortunately most often broken during the
471 mechanical preparation process). The ribs are generally quite flexible: projected forward near

472 the umbilical wall, they straighten between the first third and half of the flank. They do not
473 pass through the siphonal area or are much erased and broaden there because of the
474 thickening-out associated with the nodular appearance of the adjacent periventral tubercle.

475 - Stage 3 'with spiny periventral tubercles', up to $D=56-70$ mm in microconchs and
476 $D=95-115$ mm in macroconchs, is close to the previous stage with an even less regular and
477 flexuous ornamentation. The ribs are hardly differentiated in slender specimens. The tubercles
478 are thorny and lose the nodular appearance of the previous stage. This stage is mainly marked
479 by the irregular appearance of the trituberculation (lateral tubercle) from $D=40$ and 50 mm
480 respectively in the robust and slender microconch specimens, and $D=55$ mm in the
481 macroconchs. Note that the lateral tubercle is absent in very slender specimens. As in the
482 previous stage, all tubercles are extended by long, well-developed spines.

483 - Stage 4 'adult', up to $D=78-90$ mm for microconchs and $D=135-159$ mm for
484 macroconchs (reconstructed up to $D=165$ mm on specimen DBT.BB52, see below – Fig. 8).
485 The ornamentation becomes again a little more flexible than in the previous stage, with very
486 well individualized trituberculate main ribs, especially in macroconchs. They are much
487 reinforced with strong tubercles in robust specimens, especially the macroconchs, and a little
488 less in slender specimens and microconchs. All the ribs strengthen on the ventral area.
489 Duplication of the main ribs is frequent. In some microconchs, the ribs may become stronger
490 and become slightly spaced. The adult body chamber starts at $D=55-65$ mm in microconchs
491 and $D=94-100$ mm in macroconchs. At this stage again the tubercles are extended by spines.

492 **Dimorphism.** Among the 42 macroconchs identified, four appear almost complete and can be
493 considered as adults (preservation of stage 4 with approximation of the reinforced main ribs
494 and more marked adoral projection): (1) the specimen DBT.BB52 is the largest with 140 mm
495 in diameter ($D_{ph}=100$ mm – Fig. 8) and a body chamber preserved on $1/4$ of a whorl
496 (reconstructed at more than $1/3$, it would measure approximately $D=165$ mm in diameter); (2)

497 DBT.BB48 (Fig. 7a-b) and (3) DBT.BG58 of which only the end of the body chamber is
498 missing (respectively $D_{ph}=94$ and 99.82 mm). (4) Specimen DBT.BG49 (Fig. 11) is an
499 almost complete adult body chamber of 159 mm in diameter. Specimen DBT.BB55a (Fig. 9a)
500 is also a macroconch, but it is almost wholly septate with a 72 mm diameter phragmocone,
501 suggesting that it is probably an immature specimen. The other macroconchs are more
502 fragmentary, but the ontogenic stage reached according to the diameter (often the ornamental
503 'adult' stage present on the body chamber) makes it possible to identify them.

504 Forty-three sufficiently complete microconchs have been identified. The most complete are
505 specimens POM 219.2 ($D=86$ mm – Fig. 12a-b) and BDT.BB49 ($D=78$ mm – Fig. 7c-d), with
506 a complete (adult) body chamber more than $1/3$ of a whorl and a phragmocone around 55 mm
507 in diameter, and DBT.BG50 ($D=78.4$ mm – Fig. 10a), which shows approximated septa. Five
508 other specimens present their phragmocone and at least part of the body chamber
509 (DBT.BB54, DBT.BB57 to DBT.BB61 and FSL 487736g – Figs. 7f-g, 9b-c). The last
510 specimens are fragments of body chambers alone (DBT.BB74) or showing the transition with
511 the phragmocone (DBT.BB75).

512 The last 38 specimens are either juveniles that have not reached a sufficient development to
513 be able to be attributed to one or the other dimorph, or too incomplete specimens that do not
514 show the diameter of transition between the ontogenic stages. In all cases, below 45 mm in
515 diameter the both antidimorphs are identical. Visually, the dimorphs can only be separated on
516 the basis of their adult size and the ontogenetic stages achieved according to the diameter, but
517 neither by the dimensional parameters of the shell nor by the aspect of the ornamentation (at
518 equivalent stage).

519 The suture line is very indented and follows the ELUI formula (terminology of Wiedmann,
520 1966), with $L>E>U$. The lateral lobe L is trifid, well developed, relatively symmetrical and
521 deep. The umbilical lobe U is also trifid, shallower than L and more stocky. The siphonal lobe

522 E is barely visible due to the compaction of the specimens. The lateral and umbilical saddles
523 are well incised by an accessory lobe.

524 **Discussion.** The specimen of *Crioceratites* sp. described by Faraoni et al. (1997, p. 69, pl. 7,
525 fig. 17) from the Marche Apennines (Mt Catria, Maiolica Formation, central Italy) could
526 belong to the species *C. claveli* sp. nov. (microconch) because of its morphology, the presence
527 of main trituberculate ribs at least from D=35 mm (the very inner whorls are poorly
528 preserved), the presence of nodular lateroventral tubercles, which encompass several ribs
529 before the onset of trituberculation, and the presence of long well-defined spines. This
530 specimen is from bed 407 of the Chiaserna section assigned to the *A. radiatus* Zone (non-
531 basal) by Faraoni et al. due to the presence of *Tescheniceras flucticulus* (Thieuloy, 1977) and
532 *Spitidiscus meneghini* (Rodighiero, 1919) respectively in beds 392 and 405. The last terms of
533 the geological section could actually be more recent, since at La Charce these species are
534 reported up quite high in the *A. radiatus* Zone, and even up to the base of the current *C. loryi*
535 Zone (= new *C. claveli* Zone, this work) for *S. meneghini* (Reboulet, 1996, fig. 23). Under
536 these conditions, it is highly probable that bed 407 of the Chiaserna section is to be assigned
537 to the base of the current *C. loryi* Zone (= new *C. claveli* Zone, this work).

538
539 *C. claveli* sp. nov. is closely related to *C. loryi*. The double acme in the distribution of *C. loryi*
540 (LCH/219-220 and LCH/230-235) recorded by Reboulet (1996) at La Charce and at the
541 Cheiron ravine (CHE/179-180 and CHE/194-195 – this work) is a result which led to a more
542 careful attention in order to verify whether these two acmes could correspond to two different
543 species or if the total vertical distribution corresponds to the solely species *C. loryi*. The
544 present work clearly goes in favor of the first hypothesis. The differences between *C. claveli*
545 sp. nov. and *C. loryi* are mainly focused on the ontogenic stages and the systematic presence
546 of highly developed spines in *C. claveli* sp. nov. (Figs. 7a-b, c, g, 10a-c). In *C. loryi*, the

547 'initial trituberculate' stage 1 is shorter (5-7 mm), stage 2 is very characteristic with the
548 systematic presence of numerous fasciculated dense and homogeneous ribs, almost all similar,
549 starting from the periumbilical tubercle. This fasciculate pattern is much rarer in *C. claveli* sp.
550 nov. and always limited to a few ribs only. The stage 3 in *C. loryi* shows very discrete
551 trituberculation only on the extremely rare hyper-robust specimens; the ornamentation is more
552 regular with a periumbilical tubercle always more discreet than in *C. claveli* sp. nov. Finally,
553 in stage 4 (adult) of most macroconchs (and much more discreetly in microconchs and hyper-
554 slender macroconchs) the main ribs are clearly trituberculate in *C. claveli* sp. nov., with a
555 sometimes very developed lateral tubercle extended by a long spine (as for example in the
556 specimen BB48 – Fig. 7a-b), while the ribs are most often bituberculate in *C. loryi*. In some
557 rare macroconchs of this latter species, trituberculation can be developed irregularly and
558 fleetingly at the end of stage 4 with an always inconspicuous and unsystematic lateral tubercle
559 that never shows the presence of a spine. In terms of adult size, *C. loryi* appears to be larger
560 (105 mm versus 90 mm for microconchs and 180 mm versus 165 mm for macroconchs, see
561 Fig. 6a), although this maximum size is not expressed in all adult macroconchs of *C. loryi*.

562
563 *C. curnieri* has a more variable coiling between a crioconic to a subaspinoceratic pole.
564 However, the coiling of *C. claveli* sp. nov. is narrower and more regular since *C. curnieri*
565 shows an increase in the uncoiling of the adult body chamber at the start of a shaft and a short
566 hook (elliptical coiling), even in the case of the crioconic morphology. In all cases, *C. curnieri*
567 is bituberculate, or even monotuberculate, without ever being trituberculate as in *C. claveli* sp.
568 nov. Tuberculation is always very inconspicuous, unlike *C. claveli* sp. nov. in which every
569 tubercles is prolonged by a well-developed spine. The ornamentation of *C. curnieri* is more
570 regular in the alternation between the main and intercalary ribs. The periventral tubercles
571 appear later in ontogeny, after the periumbilical tubercles (Ropolo, 1992, p. 67), which is not

572 the case in *C. claveli* sp. nov. where the innermost whorls are trituberculate (stage 1). Then,
573 the lateral tubercle disappears, making concomitant both the two periventral and periumbilical
574 tubercles (stage 2), before its subsequent reappearance at stage 3. Adult stage 4 is also
575 different, despite the strengthening of the main and secondary ribs in *C. curnieri*, which are
576 more and more similar and spaced (sometimes bifurcated on the top of the flanks as can also
577 be observed in some specimens of *C. claveli* sp. nov.), and despite the presence of
578 constrictions. The ribs, on the other hand, remain there clearly differentiated and more spaced
579 in *C. claveli* sp. nov.; in macroconchs, the tubercles are clearly reinforced. Finally, *C. curnieri*
580 is more recent, from the *Olcostephanus jeannoti* Subzone, and mostly in the *Lyticoceras*
581 *nodosoplicatum* Zone (Ropolo, 1992; Bulot, 1995).

582
583 *C. claveli* sp. nov. is very close to *C. jurensis*, with an adult size that could be comparable on
584 the basis of our current data. The coiling is identical between the two species. Ontogenically,
585 the stages are on average shorter in *C. claveli* sp. nov. (stage 1: 9 mm vs. 15-20 mm; stage 2:
586 45-50 mm vs. 50-55 mm; stage 3: 95-115 mm vs. 110-130 mm). Both species are
587 trituberculate at stage 3, from roughly the same diameter. In *C. claveli* sp. nov., the
588 ornamentation is generally less regular, with slightly more flexuous ribs. Rib bifurcations at
589 the umbilical tubercle (fasciculation) are only exceptional in *C. jurensis*. Unlike *C. claveli* sp.
590 nov., we do not observe in *C. jurensis* the peculiar appearance of the periventral tubercles
591 which encompass several ribs so as to form a fibula, although they are nodular in both
592 species. Rib bifurcations on the upper flanks of the adult body chamber (stage 4) are rare in
593 the both species. Finally, *C. jurensis* is older than *C. claveli* sp. nov. (late *Acanthodiscus*
594 *radiatus* Zone).

595

596 *C. claveli* sp. nov. has certain affinities with *C. heterocostatus* (= *C. primitivus*). However,
597 some specimens of *C. heterocostatus* present a marked uncoiling of the body chamber, which
598 gives them a general elliptical shape (aspinoceratic, see Reboulet, 1996, pl. 24, fig. 1); this is
599 never the case in *C. claveli* sp. nov. whether in micro- or macroconch specimens. The
600 ontogeny of *C. heterocostatus* is different, with a single trituberculate stage (stage 1) longer in
601 the innermost whorl (20-30 mm vs. 9 mm), whereas in *C. claveli* sp. nov. the lateral tubercle
602 comes back at stage 3 to be well expressed in the adult body chamber. Ornamentally
603 speaking, in *C. heterocostatus* the fasciculate pattern of stage 2 is made with bundles of
604 usually two ribs starting from the umbilical tubercle. But unlike *C. claveli* sp. nov. in which
605 we also recognize this tendency, in *C. heterocostatus* these tubercles show a characteristic
606 lengthening in the direction of the rib that carries it (character known in the ‘*Sarasinella*’
607 Uhlig, 1905 of the late Valanginian – see Reboulet, 1996, p. 170). *C. heterocostatus* shows
608 more radial ribs than in *C. claveli* sp. nov., but also more bifurcations of the ribs on the top of
609 the flanks at stage 4 ‘adult’ (without being numerous). Ornamentation is interrupted at the
610 siphonal edge, even at stage 4 (except in putative macroconchs), unlike *C. claveli* sp. nov.
611 where all the ribs systematically pass over the ventral area on the body chamber. Both species,
612 as well as *C. loryi*, show the duplications of the main ribs on the adult body chamber (stage
613 4). *C. claveli* sp. nov. consistently has long and developed spines from all tubercles, which
614 does not appear to be the case in *C. heterocostatus*. Finally, *C. heterocostatus* is older than *C.*
615 *claveli* sp. nov., since this species is recorded in the late Valanginian *Criosarasinella*
616 *furcillata* Zone.

617

618 The relatively open coiling with a fairly low growth in whorl height known in *D. coniferus*,
619 associated with the total absence of fasciculation and the constant trituberculation of the main
620 ribs throughout ontogeny, which are regularly interspersed with numerous smooth ribs,

621 discard this species from the genus *Crioceratites* stricto sensu to which *C. claveli* sp. nov.
622 belongs.

623

624 **6. Biometric and statistical analyzes of *Crioceratites claveli* sp. nov.**

625

626 **6.1. Univariate and bivariate analyses**

627

628 The three histograms H/D, U/D and U/H (Fig. 13) of the univariate analysis are clearly
629 unimodal, relatively symmetrical and agree with a normal distribution (Shapiro-Wilk tests
630 respectively of $W=0.9823$, $p=0.8215$; $W=0.9705$, $p=0.4585$ and $W=0.9793$, $p=0.7359$): the
631 assumption of the homogeneity of the sample is not challenged on the basis of the univariate
632 analysis.

633

634 In the framework of the bivariate analysis (Fig. 14), the regression curves of the relations
635 between H and U as a function of D show an harmonic growth according to the function
636 $Y=bD^a$, with a significantly different from 1 ($p<<0.05$), indicating an allometric growth of the
637 shell. The dispersion is low around the mean (coefficients of determination $R^2>0.98$): the
638 results are therefore very significant and the hypothesis of the homogeneity of the sample is
639 reinforced (one single growth curve). However, we observe a slight disparity in the plot
640 distribution between microconch and macroconch specimens on the diagrams for the values
641 of U (mainly U/H), with a cluster associated with the high values of U/D and U/H in the
642 microconchs. This latter ratio was recommended by Marchand (1986) to detect a possible
643 bimodality associated with sexual dimorphism. In ammonites, dimorphism is generally
644 characterized by a difference in coiling between the antidimorphs: at the acquisition of sexual
645 maturity, and at equivalent diameter, the microconch generally has a more open umbilicus due

646 to the decreasing whorl height from its dorsal edge. Here, this feature is very weak and was
647 not highlighted by the descriptive analysis only; this shows the importance to perform a
648 biometric analysis whenever possible.

649 The $h=f(D)$ diagram shows a very strong linear increase in the spiral hiatus as a function of
650 the diameter, but the dispersion is important ($R^2=0.68$), which shows the great variability of
651 this parameter.

652 The $Nt/2$ and $Ni/2$ diagrams show a relative stability in the number of ribs per half-whorl
653 during growth, although this parameter is extremely variable (large dispersion around the
654 mean curve).

655

656 **6.2. Multivariate analysis**

657

658 A Principal Component Analysis (PCA – Fig. 15) was performed. The parameters h and $Nt/2$
659 have a distribution that significantly departs from normality (grayed out in Table 3). The
660 Dornik and Hansen omnibus test shows departure from normality for the data taken as a
661 whole ($p \ll 0.05$), which requires the log transformation of the data to practice the PCA in
662 order to normalize their distribution, reduce heteroscedasticity and resolve the problem of
663 non-additivity of the independent variables, without modification of the variance. The
664 correlation matrix was therefore used in order to standardize the data.

665 The first 3 principal components of the PCA have an eigenvalue close or greater than 1 (4.05,
666 1 and 0.95), and they retain 85.72% of the total inertia of the variance (Table 4), of which
667 72.17% for PC1 and PC2 alone. The analysis is therefore considered relevant. The results are
668 shown in Figure 15 and Table 5. The ornamentation vectors are orthogonal to the shell
669 morphological vectors, indicating an apparent lack of correlation between these vector groups,
670 as previously recognized for some other *Crioceratites* (Ropolo, 1995; Bert, 2014a). The

671 diagram also shows an inverse correlation between H/D and the other morphological
672 parameters: the relative height decreases as a function of (1) the diameter of the shell, (2) the
673 opening of the umbilicus and (3) the spiral hiatus. These correlations are consistent with the
674 descriptive analysis and to what is expected under the intraspecific laws in ammonites (Bert,
675 2014a), even considering the lack of W data. In contrast, the PCA diagram shows an inverse
676 relationship between the number of primary and secondary ribs, which was not demonstrated
677 by descriptive analysis; this apparent relationship needs to be tested (see below the correlation
678 by Spearman rank).

679 The convex hulls formed by the antidimorphs recognized during descriptive analysis overlap
680 widely. Even though the distribution of plots shows that macroconchs are more influenced by
681 PC1 than microconchs, the distinction observed in bivariate analysis (Fig. 14) with respect to
682 the high values of U/H and U/D in microconchs is not found in the plot distribution on the
683 PCA (Fig. 15). This lack of graphic discrimination is essentially due to the fact that the U/H
684 and U/D vectors have the same orientation as the D and h vectors, which favors the
685 superposition of the plots associated with the microconchs with those of the large
686 macroconchs. Thus, the largest positive values of the parameters related to the size (D and h)
687 override the parameters related to the opening of the umbilicus. On PC2, on the other hand,
688 the microconchs are even more influenced than the macroconchs by the ornamental
689 parameters. Indeterminate antidimorphs form a group opposed to the D vector, which is
690 logical since only very small specimens are affected by this group (see reasons in descriptive
691 section, Chapter 5).

692

693 In addition to the PCA, a correlation test by Spearman rank (r_s) was performed in order to
694 verify and quantify the relationships between the variables. The results (Table 6 and Fig. 15)
695 confirm the descriptive analysis and partially the PCA; they clearly show for this group of

696 *Crioceratites* that the ornamental parameters are independent from the shell morphological
697 parameters (non-covariant factors – see also Bert, 2014b, p. 234). The analysis of the PCA
698 alone could suggest that the number of main tuberculate ribs would be inversely correlated
699 with the number of smooth ribs, but this point is not confirmed by the correlation by
700 Spearman rank ($r_s=0.0099851$; $p=0.96764$). Ornamental parameters also do not depend on the
701 diameter.

702 On the other hand, the strong correlation between the morphological parameters of the shell
703 (including the spiral hiatus h) and the diameter is confirmed; it is positive in all cases except
704 for the relative height, which decreases proportionally with the size.

705 The frequency histogram on PC1 is unimodal and normal ($W=0.9734$, $p=0.5242$ – Fig. 15). In
706 contrast, the histogram attached to PC2 is clearly not normal ($W=0.9095$, $p=0.006$). The
707 explanation lies to the fact that the two dimorphs are well discriminated by the analysis, even
708 if they do not stand out very clearly graphically on the PCA, whose distribution of points is
709 rather homogeneous.

710
711 The morphological differences between the antidimorphs recognised by the descriptive
712 analysis were statistically tested by an analysis of similarity (ANOSIM, Hammer and Harper,
713 2006 – Table 7) with 100,000 permutations. This non-parametric test is more suitable for
714 small samples than a multivariate non-parametric analysis of variance (NPMANOVA –
715 Anderson, 2001). To ensure the homoscedasticity between the variables, they were
716 standardized to mean zero and unit standard deviation (Quinn and Keough, 2002, p. 415). Our
717 data are standardized measures, thus Euclidean distance was used to perform the ANOSIM
718 (Quinn and Keough, 2002, p. 409). Pairwise comparison was performed only as a post hoc
719 test (in case of $p<0.05$) with sequential Bonferroni significance of pairwise comparison p
720 values (Table 8) in order to reduce type I errors (Hammer and Harper, 2006, p. 36).

721

722 Consistently with the rest of the study, statistically significant differences were found between
723 the both recognized antidimorphs based on descriptive analysis, but logically not with the
724 indeterminate group which acts somewhat as a control group.

725

726 **7. Intraspecific variation in *Crioceratites claveli* sp. nov.**

727

728 **7.1. Background on the laws of intraspecific variability in ammonites**

729

730 Ammonites shells are known to display a sometimes significant morphological intraspecific
731 variability (see synthesis in De Baets et al., 2015). The laws of intraspecific variability in
732 ammonites can be generalized (Bert, 2019) and relate to at least 8 potential factors of
733 variation, separated into two categories:

734 - (1) Discontinuous variability:

735 - changes between sexual dimorphs can affect shell size, coiling, peristome
736 appearance, ornamentation, or combinations;

737 - non-sexual polymorphism can concern a particular character (for example:
738 supernumerary tubercle);

739 - fluctuating asymmetry results from the inability of species to absorb ecological stress
740 during their development;

741 - dextrality/senestria is linked to chirality.

742 - (2) Continuous variability:

743 - variations in the rate of development modulate the expression of ontogeny
744 (heterochronies) and can restructure the shell by simple shift if the stages involved are of
745 sufficiently different morphologies (see synthesis in De Baets et al., 2015);

746 - the secondary erasing of the ornamentation does not seem to depend on any other
747 intrinsic factor (probable role of the environment – see Bersac and Bert, 2012);

748 - variation in the coiling (heteromorphy) is unstable depending on the groups, and
749 could also reflect the influence of the environment (Reboulet et al., 2005; Bert and Bersac,
750 2013);

751 - multipolar variation is one of the most important in ammonites. It results from the
752 generalization in two (²) or three (³) poles of the historical law known as the ‘1st Buckman
753 law’ (Westermann, 1966) now outdated, which shows a correlation (to varying degrees and
754 not always in the same direction) between the robustness of the ornamentation, the thickness
755 of the section, the height of the whorl and the opening of the umbilicus; the extreme poles are
756 interconnected by all the intermediaries. Other examples of multipolarity (order⁸) have been
757 described recently in the literature in the Crioceratitidae *Balearites* Sarkar, 1954 /
758 *Pseudothurmannia* Spath, 1923 (Matamales-Andreu and Company, 2019), but they arise from
759 problems of interpretation by nesting discontinuous (non-sexual polymorphism concerning a
760 supernumerary tubercle) and continuous factors (heteromorphy and ‘classic’ multipolar
761 variation of order²).

762 These different factors of variation may or may not be expressed simultaneously and be
763 covariant with each other (example of morphological-dependent heterochronies – Bert,
764 2014a). A few exceptional cases seem to deviate from these laws: the significant anarchic
765 variation of *Chelonicerias cornuelianum* (d'Orbigny, 1841) (Douvilleiceratidae Parona and
766 Bonarelli, 1897) from the lower Aptian of the Argiles à Plicatules Formation (Bersac and
767 Bert, 2018), can be explained by the context of exceptional environmental stress in connection
768 with the Oceanic Anoxic Event 1a (OAE1a – Schlanger and Jenkyns, 1976; Arthur et al.,
769 1985; and see discussion in Bersac and Bert, 2018). Subsequently, the *Douvilleicerias* de
770 Grossouvre, 1894 took up a classic multipolar variation (Courville and Lebrun, 2010).

771 In the case of the *Crioceratites*, the observed variability relates to dimorphism, multipolar
772 variation and heterochronic variation. Significant variations in the type of coiling, such as for
773 example in *C. curnieri* (see Ropolo, 1992) have not been observed in *C. claveli* sp. nov.

774

775 **7.2. Laws of intraspecific variability applied to *C. claveli* sp. nov.**

776

777 **7.2.1. Dimorphism**

778

779 The study of abundant material of *C. claveli* sp. nov. (this work) made it possible to highlight
780 the presence of two distinct morphologies, interpreted here as sexual dimorphs (for example,
781 compare Figs. 7a-b, 8 versus Figs. 7c-d, 12a-b). Both the two antidimorphs are present on the
782 same sites studied, in the same samples, have the same stratigraphic distribution, present the
783 same ornamental characteristics, substantially the same characteristics of shell morphology
784 and above all have the same ontogenetic succession (except for heterochronic variations).
785 This dimorphism was clearly recognized in the descriptive analysis based on the diameter
786 reached by the different ontogenetic stages by the two antidimorphs. Biometrics (bivariate
787 analysis – Fig. 14) and statistical analyzes (ANOSIM – Table 7) subsequently made it
788 possible to reinforce this result and to highlight small differences in construction concerning
789 the relative umbilicus (U/H and U/D), not detected by the descriptive analysis alone: at
790 equivalent diameter, the microconchs have values of these parameters very slightly higher
791 than those of the macroconchs. Note that before the end of ontogenetic stage 2, at an average of
792 about 45 mm in diameter, it is not possible to discriminate the antidimorphs. Without taking
793 into account individuals which are too small (1/3 of the sample) the observed sex ratio seems
794 close to 50%. Based on our study sample, the size ratio shows that macroconchs are on
795 average around twice the size of microconchs. This order of magnitude is relatively consistent

796 with that observed in *C. loryi* (compare Fig. 6a and c). These results confirm those obtained
797 by Ropolo (1995) who had already recognized the existence of a dimorphism in *Crioceratites*,
798 including *C. loryi* and *C. curnieri* among others, and the work of Reboulet (1996) which
799 seemed to show its existence in *C. heterocostatus* (= *C. primitivus* in Reboulet, 1996). The
800 microconch dimorph has so far not been clearly demonstrated in *C. jurensis* due to a lack of
801 specimens. By comparison with related species (*C. claveli* sp. nov., *C. loryi*, *C. curnieri* and
802 probably also *C. heterocostatus*), where it is known, the existence of dimorphism in this
803 species is highly probable on the same way.

804

805 **7.2.2. Multipolar variation**

806

807 The inverse relationship between relative height (H/D) and relative umbilicus (U/D) has been
808 well demonstrated by multivariate analysis (Fig. 15; Table 6). This relationship is usually
809 known as the Buckman's 1st law of variation; it is common to most ammonites and represents
810 one aspect of the classical continuous multipolar variation (Bert, 2014a). There is also some
811 variation in the strength and density of the ornamental pattern: the more slender specimens
812 have markedly less rib differentiation with very inconspicuous tubercles. On the other hand,
813 the multivariate analysis shows an absence of correlation between the ornamental parameters
814 and the morphology of the shell.

815 Despite of this, continuous variation in *C. claveli* sp. nov. looks to be of the dipolar type
816 (order²), even if caution is required because of the lack of parameters based on the values of
817 W in the analysis (this work). However, it is clear that the importance of W in the
818 intraspecific variation in *Crioceratites* has never been highlighted in the literature.

819

820 **7.2.3. Heterochrony**

821

822 While the appearance diameter of the ornamental stages does not seem to depend on the
823 morphological parameters of the shell in *C. claveli* sp. nov., this is not the same for the
824 heterochronic variation. It was observed in the descriptive analysis, at least in the
825 microconchs, that the appearance of trituberculation of stage 3 during ontogeny is slightly
826 fluctuating and depends on the robustness of the ornamentation. Ontogeny is slightly delayed
827 for robust specimens and slightly accelerated for slender specimens.

828

829 **8. Biostratigraphic implications**

830

831 The discovery of *C. claveli* sp. nov. and the new understanding of the stratigraphic repartition
832 of *C. loryi*, lead us to propose some changes in the biostratigraphic chart currently admitted
833 for the early Hauterivian. This proposal for the south-eastern France may have extension
834 potential for the Mediterranean Province of the Mediterranean Caucasian Subrealm (Tethyan
835 Realm).

836

837 ***Crioceratites claveli* Zone (new)**

838 **Index species.** *Crioceratites claveli* sp. nov.

839 **Reference section.** The Cheiron ravine (CHE, see Chapter 4.1) in the Castellane area
840 (southeastern France, Vocontian Basin) with the beds interval 179-212. This interval is
841 correlable to the bundle comprising the beds 219-241e of the La Charce-Pommerol sections
842 (see Chapter 4.2 and Aguirre-Urreta et al., 2019, fig. 8). Note that at La Charce, the bed
843 succession is disturbed by a slump at the boundary between the *C. claveli* (new) and *L.*
844 *nodosoplicatum* zones.

845 **Status.** The finding of *C. claveli* sp. nov. in a stratigraphic position that was once considered
846 to be the first acme of *C. loryi*, gives rise to some reflections since it appears that *C. claveli*
847 sp. nov. is de facto the base marker of the current *C. loryi* Zone (for example see Bulot, 1995;
848 Reboulet, 1996). Note that *C. claveli* sp. nov. shows a vertical distribution widely beyond its
849 FO, since it extends to the second acme of the genus (at the top part of the current *C. loryi*
850 Subzone; see Reboulet, 1996 for the quantitative approach of the 2 acmes). *C. loryi* does not
851 exist at the base of its current zone and it only appears during the second acme of the genus,
852 to disappear a short time later.

853 These findings allow us to propose the new *C. claveli* Zone instead of the *C. loryi* Zone for
854 the Vocontian Basin (Table 9). Its lower limit is defined by the First Appearance Datum
855 (FAD) of *C. claveli* sp. nov. and its upper limit by the FAD of *L. nodosoplicatum* (in the
856 Cheiron reference section the FO of *C. claveli* sp. nov. is recorded in bed 179, and in the bed
857 219 of the La Charce and Pommerol sections). This proposal has the advantage of avoiding
858 any possible confusion between the former *C. loryi* Zone and a new definition that the
859 revision of the stratigraphic distribution of its index species would have led.

860 The stratigraphic distribution of *C. claveli* sp. nov. is precisely known, and because of its high
861 frequency (mainly in pelagic deposits; there apparent absence from the peri-Vocontian
862 platform borders are due to lacks in the deposits – see Bulot, 1995, p. 93-94) it is a serious
863 and legitimate candidate to the status of index species. Its potential for long-distance
864 correlations has now to be tested outside the Vocontian Basin, but its presence is also attested
865 in Italy (Faraoni et al., 1997 and see descriptive section in Chapter 5).

866 **Faunal assemblage.** See below for the new *C. claveli* Subzone, and Reboulet (1996, fig. 23)
867 and Aguirre-Urreta et al. (2019, fig. 8) for the *O. jeannoti* Subzone.

868

869 ***Crioceratites claveli* Subzone (new)**

870 **Index species.** *Crioceratites claveli* sp. nov.

871 **Reference section.** The Cheiron ravine (CHE, see Chapter 4.1) in the Castellane area
872 (southeastern France, Vocontian Basin), with the beds interval 179-197. This interval is
873 correlable to the bundle of beds 219-231 of the la Charce-Pommerol sections (see Chapter 4.2
874 and Aguirre-Urreta et al., 2019, fig. 8).

875 **Status.** For the same reasons as for the new *C. claveli* Zone, it is necessary to replace the *C.*
876 *loryi* Subzone with the new *C. claveli* Subzone. Its lower limit is defined by the FAD of *C.*
877 *claveli* and its upper limit by the FAD of *O. jeannoti*. Within the new *C. claveli* Subzone of
878 the Cheiron ravine and the La Charce-Pommerol sections, certain beds or bundles of beds are
879 noticeably rich in representatives of the genus *Crioceratites*. We propose to recognize them as
880 interval horizons; they are as follows:

881 - (1) the *C. claveli* lower interval Horizon (CC1 in Fig. 2): at the Cheiron ravine, it is
882 represented by the bed 179 (= bed 219 in the La Charce-Pommerol sections), of which the
883 lower limit is the First Occurrence (FO) of *C. claveli*. This horizon corresponds to the first
884 acme of the genus *Crioceratites* evoked previously;

885 - (2) the *C. claveli* upper interval Horizon (CC2 in Fig. 2): at the Cheiron ravine, it is
886 represented by the beds 194 and 195 (their exact correspondence in the La Charce-Pommerol
887 sections is not yet clear, probably around the bed 229). The latter is the bed with the Last
888 Occurrence (LO) of *C. claveli* sp. nov.;

889 - (3) the *C. loryi* interval Horizon (CL in Fig. 2): at the Cheiron ravine, it is
890 represented by the beds 196 (containing the FO of *C. loryi*) and 197 (= beds 230-231 in the La
891 Charce-Pommerol sections).

892 Both the upper *C. claveli* and *C. loryi* interval horizons represent the second acme of the
893 genus *Crioceratites* evoked previously.

894 **Faunal assemblage.** *C. claveli* sp. nov. dominates largely the ammonite faunas of both the
895 two *C. claveli* lower and upper interval horizons. The index species is present but rarer in the
896 rest of its zone, especially compared to *Neolissoceras grasianum* for example. The other
897 ammonites found in the subzone are (Fig. 2): *Phyllopachyceras winkleri* (Uhlig, 1882), *Ph.*
898 *infundibulum* (d'Orbigny, 1841), *Hypophylloceras tethys* (d'Orbigny, 1841), *Protetragonites*
899 *cf. quadrisulcatus* (d'Orbigny, 1841), *Olcostephanus sayni* (Kilian, 1896), *Spitidiscus*
900 *meneghinii*, *Bochianites kiliani* Turner, 1962, *Himantoceras* sp., *Oosterella* sp. and *Saynella*
901 *aff. clypeiformis* (d'Orbigny, 1841). In the *C. loryi* interval Horizon, the latter species replaces
902 *C. claveli* sp. nov. and dominates largely the ammonite fauna. We can also notice the presence
903 of *Lyticoceras* sp. nov., *Valdedorsella* sp. and *Davouxiceras aff. sablieri* (Astier, 1851).

904

905 **9. Conclusions**

906

907 (1) The research carried out in the Lower Cretaceous series of south-eastern France
908 (Vocontian Basin) made it possible to highlight the two acmes of the genus *Crioceratites*
909 during the former *C. loryi* Zone (early Hauterivian), so far reported to the single species *C.*
910 *loryi*. The first acme marks the beginning of the zone and was considered to correspond more
911 or less to the appearance of the genus *Crioceratites* in the early Hauterivian despite the
912 existence of older representatives of this genus in the late Valanginian (Reboulet, 1996).
913 However, only *Crioceratites* of the 2nd acme were depicted in the literature. The new
914 material from the classic Cheiron ravine site (Alpes de Haute-Provence), as well as the
915 revision of the material cited by Reboulet (1996) from the former *C. loryi* Zone of the La
916 Charce (Hauterivian GSSP) and Pommerol (Drôme) reference sections, revealed that only
917 part of the second acme actually belongs to *C. loryi*. The *Crioceratites* from the interval
918 between the first acme and the first part of the second acme belongs to *C. claveli* sp. nov. only

919 (including the specimen of *C. sp.* depicted by Faraoni et al., 1997); *C. claveli* sp. nov. and *C.*
920 *loryi* relay each other in the stratigraphy. An interesting point is that *C. claveli* sp. nov. shows
921 a great morphological and ornamental stability between its appearance and disappearance,
922 while the shift to *C. loryi* seems particularly sudden.

923

924 (2) *C. claveli* sp. nov. and *C. loryi* are differentiated mainly by the duration of the ontogenic
925 stages reached during growth and by the presence of a marked spiny trituberculation in *C.*
926 *claveli* sp. nov. The abundant material from the *C. claveli* lower interval Horizon (the first
927 acme) allowed a detailed analysis of the variation of this species for a very short period of
928 time (avoiding time-averaging). Under the laws of intraspecific variability in ammonites, 3
929 factors are currently known in *C. claveli* sp. nov.:

930 - the dimorphism has been recognized by palaeontological analysis (description of the
931 both macro- and microconch morphs), biometry (discrimination of the both dimorphs on the
932 U/D and H/D crossplots) and statistics (ANOSIM and pairwise comparison). The observed
933 sex ratio is around 50%;

934 - the multipolar variation of order² with an inverse correlation between the relative
935 height and the relative umbilicus between two poles (morphological parameters) corresponds
936 only partially to the classic Buckmann's 1st law of covariation since the robustness of the
937 ornamentation (ornamental parameter) is here independent from the shell morphological
938 parameters (non-covariant factors);

939 - the heterochronies concern the onset diameters of the ontogenic stages depending on
940 the robustness of the ornamentation but not on the morphological parameters of the shell
941 (ontogeny is slightly delayed for robust specimens and slightly accelerated for slender
942 specimens).

943

944 (3) The analysis of the stratigraphic distribution of *C. claveli* sp. nov. and *C. loryi* leads us to
945 propose the new *C. claveli* Zone and Subzone to replace the *C. loryi* Zone and Subzone for
946 the south-east of France. This proposal seems preferable to avoid a revision of the *C. loryi*
947 Zone, which would lead to confusion with its current definition. Three interval horizons are
948 recognized: the *C. claveli* lower interval Horizon (= the first acme of the *Crioceratites*); the *C.*
949 *claveli* upper interval Horizon (= the first part of the second acme of the *Crioceratites*, which
950 corresponds with the LO of *C. claveli* sp. nov.); and the *C. loryi* interval Horizon (= the
951 second part of the second acme of the *Crioceratites*, which corresponds with the FO of *C.*
952 *loryi*). The presence of *C. claveli* sp. nov. at least in France (this work) and Italy (*Crioceratites*
953 sp. in Faraoni et al., 1997) is a first step towards a generalization of this zonal proposal for the
954 Mediterranean Province of the Mediterranean Caucasian Subrealm (Tethyan Realm).

955

956 (4) The northern edge of the Provençal platform (neritic zone of the Arc de Castellane)
957 delivered some *Crioceratites* s. str. from the top part of the *A. radiatus* Zone, thus reducing
958 the gap between the older *Crioceratites* of the uppermost Valanginian and those of the new *C.*
959 *claveli* Zone. The specimens collected all belong to the species *C. jurensis*, which is
960 rehabilitated and revised in this work, making it possible to refuse its synonymy with
961 *Davouxiceras nolani* as proposed by Sarkar (1955 – see also Klein et al., 2007, p. 70): the
962 type of *C. jurensis* is figured here for the first time since the original drawing by Pictet and
963 Campiche (1861).

964

965 **Acknowledgments**

966 The authors would thank all the persons that helped for the field sampling in the Cheiron
967 ravine: Francesco Bariani, Rémi Marongiu(†) and Pierre-Jean Bernard (Departmental Council
968 of the Alpes de Haute-Provence). The Réserve naturelle nationale géologique de Haute-

969 Provence and the Department Prefecture provided the search authorizations in the protected
970 area. Lionel Cavin is warmly acknowledged for his help to find the type specimen of
971 *Crioceratites jurensis* and for sending us a cast. Fabienne Giraud is acknowledged for the
972 sending of the cast and photos of the type specimen of *Crioceratites loryi*. Finally, we warmly
973 thank both the two reviewers, Josep Anton Moreno-Bedmar and Yves Dutour, and the
974 Associate Editor Marcin Machalski for their very constructive comments.

975

976 **Funding**

977 This work was supported by the Departmental Council of the Alpes de Haute-Provence,
978 France.

1185 **Captions of the figures:**

1186 **Fig. 1.** Palaeogeographic map of the Vocontian Basin for the Hauterivian (southeastern France, modified after
 1187 Arnaud, 2005). The stars point out the sections mentioned in the text: CAR = Rougon; CHE = the Cheiron
 1188 ravine; COU1 = Bargème; ESC = Escragnoles; LCH = La Charce GSSP; POM = Pommerol; PV2 = La Palud-
 1189 sur-Verdon.

1190 **Fig. 2.** Lithology of the Cheiron ravine (CHE) with ammonite fauna and biostratigraphy (this work). The interval
 1191 horizons highlighted in this section are: CC1 = *Crioceratites claveli* lower interval Horizon; CC2 = *Crioceratites*
 1192 *claveli* upper interval Horizon; CL = *Crioceratites loryi* interval Horizon.

1193 **Fig. 3.** *Crioceratites jurensis* (Nolan, 1894), cast of the type specimen MHNG GEPI 16787, section ESC,
 1194 *Acanthodiscus radiatus* Zone. The arrow points out the end of the phragmocone.

1195 **Fig. 4.** *Crioceratites jurensis* (Nolan, 1894), specimen DBT.BC47, section CAR, upper part of the
 1196 *Acanthodiscus radiatus* Zone; c is face B of the body chamber of the same specimen. The arrow points out the
 1197 end of the phragmocone.

1198 **Fig. 5.** *Crioceratites jurensis* (Nolan, 1894), specimen LCT.7Z, section PV2, upper part of the *Acanthodiscus*
 1199 *radiatus* Zone. The arrow points out the end of the phragmocone.

1200 **Fig. 6.** *Crioceratites loryi* (Sarkar, 1955); a-b: macroconch specimen DBT.AV98 from the Moriez area; c-d:
1201 microconch specimen DBT.BB50 from the Moriez area; e: microconch specimen DBT.BB84 from CHE, bed
1202 197. All the specimens are from the *Crioceratites loryi* interval Horizon in the new *Crioceratites claveli* Zone
1203 and Subzone. The arrows point out the end of the phragmocone.

1204 **Fig. 7.** *Crioceratites claveli* sp. nov.; a-b: macroconch specimen DBT.BB48, holotype; c-d: microconch
1205 specimen DBT.BB49; e: microconch specimen DBT.BB65; f: microconch specimen DBT.BB60; g: microconch
1206 specimen DBT.BB57. All the specimens are from CHE, bed 179, in the *C. claveli* lower interval Horizon, new
1207 *C. claveli* Zone and Subzone. The arrows point out the end of the phragmocone.

1208 **Fig. 8.** *Crioceratites claveli* sp. nov., macroconch specimen DBT.BB52, from CHE, bed 179, in the *C. claveli*
1209 lower interval Horizon, new *C. claveli* Zone and Subzone. The arrow points out the end of the phragmocone.

1210 **Fig. 9.** *Crioceratites claveli* sp. nov.; a: macroconch specimen DBT.BB55; b-c: microconch specimen
1211 DBT.BB54, note the nodular periventral tubercles of the ontogenic stage 2. All the specimens are from CHE,
1212 bed 179, in the *C. claveli* lower interval Horizon, new *C. claveli* Zone and Subzone. The arrows point out the end
1213 of the phragmocone.

1214 **Fig. 10.** *Crioceratites claveli* sp. nov., a: microconch specimen DBT.BG50; b: microconch specimen
1215 DBT.BG51; c: macroconch specimen DBT.BG75. All the specimens are from CHE, bed 195, in the *C. claveli*
1216 upper interval Horizon, new *C. claveli* Zone and Subzone. The arrows point out the end of the phragmocone.

1217 **Fig. 11.** *Crioceratites claveli* sp. nov., macroconch specimen DBT.BG49, from CHE, bed 194, in the *C. claveli*
1218 upper interval Horizon, new *C. claveli* Zone and Subzone. The arrow points out the end of the phragmocone.

1219 **Fig. 12.** *Crioceratites claveli* sp. nov.; a-b: microconch specimen POM 219.2 from POM, bed 219, b is the
1220 mould of the imprint; c: microconch specimen FSL 487733a; d: microconch specimen FSL 487743a; e:
1221 microconch specimen FSL 487733e; f: microconch specimen FSL 487733f; g: undetermined antidimorph
1222 specimen FSL 487733j. Specimens c-f are from LCH, in bed 219; specimen g is from bed 220 of the same
1223 section. All the specimens are from the *C. claveli* lower interval Horizon, new *C. claveli* Zone and Subzone. The
1224 arrows point out the end of the phragmocone.

1225 **Fig. 13.** Diagrams of the univariate analysis. Normality curve in black, Kernel density in red (refer to the
1226 electronic version of the paper).

1227 **Fig. 14.** Bivariate analysis crossplots. Red dots: microconchs; blue dots: macroconchs; black dots: undetermined
1228 antidimorphs (refer to the electronic version of the paper).

1229 **Fig. 15.** Diagrams of the multivariate analysis: principal component analysis crossplot, 'loading' of the variables
1230 on the first two Principal Components, frequency histograms of the projections of the plots on the first two PC
1231 and matrix of the Spearman's rank correlation. Red dots: microconchs; blue dots: macroconchs; black dots:
1232 undetermined antidimorphs; normality curve in black, kernel density in red (refer to the electronic version of the
1233 paper).

1234

1235 **Caption of the tables:**

1236 **Table 1.** Measurements of the main specimens of *Crioceratites jurensis*. In bold are the diameters expected
1237 adult.

1238 **Table 2.** Measurements of the main specimens of *Crioceratites claveli* sp. nov. In bold are the expected adult
1239 diameters.

1240 **Table 3.** Normality tests of the multivariate analysis.

1241 **Table 4.** Variance and eigenvalue reached by the principal components.

1242 **Table 5.** Loading of the variables on the 7 PC.

1243 **Table 6.** Correlation by Spearman rank. In grey: dependent variables ($p < 0.05$).

1244 **Table 7.** The ANOSIM.

1245 **Table 8.** p value of the sequential Bonferoni significance: in grey are the significant differences.

1246 **Table 9.** Biostratigraphic chart.
