Mars has lost most of its initial water to space as atomic hydrogen and oxygen^{1,2}. Spacecraft measurements have determined that the hydrogen component of this loss undergoes large variations with season³⁻⁶ inconsistent with longstanding explanations^{7,8}. The cause is incompletely understood, with likely contributions from seasonal changes in atmospheric circulation, dust activity, and solar extreme ultraviolet input. While some modeling and indirect observational evidence suggest dust activity can explain the seasonal trend⁹⁻¹⁵, no prior study has been able to unambiguously distinguish seasonal from dust-driven forcing. Here we present synoptic measurements of dust, temperature, ice, water, and hydrogen on Mars during a regional dust event, demonstrating that individual dust events can boost planetary H loss by a factor of 5-10. This regional storm occurred in the declining phase of the known seasonal trend, establishing that dust forcing can override this trend to drive enhanced escape. Because similar regional storms occur in most Mars years¹⁶, these storms may be responsible for a large fraction of Martian water loss, with implications for Mars atmospheric evolution and planetary habitability in general.

1 Hints at Dust-Driven Escape

The desiccation and oxidation of Mars over the last 4.5 Gyr is a consequence of hydrogen loss to space, which was first constrained by the Mariner spacecraft¹⁷. This early work established a paradigm of slow and steady H loss with little variability^{7,8}, which has been overturned with evidence for order-of-magnitude seasonal variations by Mars Express⁴, the Hubble Space Telescope^{3,5}, and the Mars Atmosphere and Volatile Evolution (MAVEN) mission⁶. These later missions found that H loss from Mars peaks in Southern Summer, after perihelion, at rates 10-100 times larger than those in Northern Summer.

More recent investigations have explored forcing of H loss by attempting to quantify the impact of seasonal drivers and relatively rare planet-encircling (a.k.a. global) dust events on the availability of water at high altitudes. Because the data available to these studies covered a limited time period, the exact nature of the driving mechanisms was obscured and a unique attribution to seasonal vs. dust effects was not made. Heavens *et al.*¹⁰ examined the Mars Year 28 (2007) global dust event using a combination of dust and water ice cloud analysis and constraints from prior H loss estimates and found that global events have perhaps a factor of several effect on H loss (see also discussion of this result by Clarke¹⁸), but as the H loss was only observed to decrease simultaneously with the decline of the storm, the end of southern summer, and an increase in Mars-Sun distance, the driver of the loss could not be uniquely determined. Observations of the Mars Year 34 global event were more extensive, indicating atmospheric warming and subsequent enhancement of high-altitude water abundances, establishing that at least during global dust events water is not effectively cold trapped by declining temperatures with increasing altitude^{12,14,19}. Finally, tidal²⁰ and cloud^{21,22} observations suggest that water transport in general is strongly affected during global events, with the potential for enhanced loss. Recent observations from MAVEN's mass spectrometer indicate higher abundances of H-bearing ions during Southern summer and some dust events, but do not constrain escaping hydrogen or dust abundances¹⁵.

Multiple modeling studies have predicted elevated H loss as an indirect consequence of dust activity and the resulting greater abundance of high-altitude water. Chaffin *et al.*⁹ demonstrated via 1D photochemical modeling that high-altitude water concentrations of ~ 100 ppm at 60 km observed by Maltagliati *et al.*^{23,24} could induce more than a tenfold increase in H loss over the course of a week. Shaposhnikov *et al.*¹¹ presented general circulation model calculations demonstrating that interhemispheric transport in Southern Summer lofts water to high altitudes, and that this circulation is intensified during global dust events. Most recently, Neary *et al.*¹³ presented global simulations including water photodissociation and H production demonstrating that the vertical extent of dust is a powerful control on the location of the hygropause and the ability of water to rise to altitudes where it is easily photodissociated.

Our observations provide the first definitive measurements of H loss attributable to an individual lower atmospheric dust event, which we term 'impulsive' H loss. These observations were made during an annually recurring C-type regional dust event (as defined in Kass *et al.*¹⁶), which occurred in late Southern Summer of Mars Year 34 (L_s 320 – 336, where the $360^\circ L_s$ calendar begins with 0° at the Mars Northern Vernal Equinox), January-February 2019. Because this storm occurred well after southern summer solstice and perihelion when the intense seasonal Hadley circulation in the lower atmosphere and EUV insolation of the upper atmosphere were in decline, we can attribute the effects we observe to dust, eliminating the ambiguity in causes associated with

83 prior observations of enhanced H loss.

84 **2 Observations of a Regional Dust Event**

85 We combine data and retrieved atmospheric parameters from four instruments on three spacecraft
86 (Figure 1). The Mars Climate Sounder on the Mars Reconnaissance Orbiter (MRO/MCS)²⁵ is an
87 infrared radiometer observing the 0.3-45 μm spectral range from the surface to ~ 90 km, retrieving
88 atmospheric temperatures and dust and water ice opacities^{26,27}. On the Trace Gas Orbiter (TGO)
89 mission are the Atmospheric Chemistry Suite (ACS)²⁸, and Nadir and Occultation for MARS Dis-
90 covery (NOMAD)²⁹, each of which obtains solar infrared absorption spectra at the terminator,
91 retrieving water vapor to altitudes near 80 km^{12,14}. Finally, MAVEN’s Imaging Ultraviolet Spec-
92 trograph (IUVS)³⁰ observes neutral hydrogen in the thermosphere and corona at altitudes greater
93 than ~ 100 km³¹. IUVS also observes the full disc of Mars, providing global images of clouds and
94 dust. We present data from the Mars Year 34 C event alone because this is the only event in the
95 MAVEN dataset for which coverage from all three spacecraft is available. Further details of the
96 available dataset, observation geometry, and retrieval techniques employed by each instrument are
97 provided in the supplementary material.

98 In the lower atmosphere, MRO/MCS measurements show the regional dust event began near
99 L_s 320 (Mars Year 34, 8 January 2019), close to the Acidalia-Chryse storm track $\sim (22^\circ\text{S}, 32^\circ\text{W})$.
100 The event peaked near L_s 325 (15 January), and declined over the next $15 - 20^\circ L_s$ into mid-
101 February. Although we cannot completely rule out all potential lingering effects of the preceding
102 global storm, the atmosphere had largely returned to a typical seasonal state prior to the C event
103 onset³². This regional event produced a ~ 20 K temperature increase at the 5 Pa (~ 50 km) level
104 near the equator, with a ~ 40 K increase at high Southern latitudes, followed by a similar and
105 longer lasting increase near the North Polar vortex indicative of greatly increased interhemispheric
106 circulation. These warmer conditions observed at all latitudes inhibited ice condensation, and total
107 column water ice opacities dropped by a factor of three during the dust event. IUVS observed
108 this decrease in equatorial ice as the disappearance of bright clouds capping the Tharsis volcanoes,
109 which were visible above the Rayleigh scattering of the dense lower atmosphere before and after
110 the event but not near its peak.

111 In the middle atmosphere, TGO NOMAD and ACS observed little to no water at 60 km
112 before the event. Within several sols after the dust was introduced, the mid-altitude water abun-
113 dance increased by more than an order-of-magnitude to > 100 ppm in both the ACS and NOMAD
114 data, coinciding precisely with the disappearance of the equatorial clouds. Following the dust
115 peak, the TGO orbit entered a period where no occultations were possible, introducing a gap in
116 the timeline. After occultations resumed, NOMAD retrievals indicated elevated water abundances,
117 peaking about a scale height lower than before the gap, well into the declining phase of the event.
118 We provide comparisons between all retrieved water abundances as supplementary material.

119 At the highest altitudes, MAVEN/IUVS observes Lyman alpha sunlight scattered by H in
120 the thermosphere and exosphere, whose brightness is a tracer of H abundance. Simultaneous
121 with the onset of the atmospheric warming, near L_s 322, coronal brightnesses decreased. This
122 indicates suppressed H densities at high altitude resulting from less effective diffusive separation
123 of the H above the homopause, due in turn to more efficient mixing at the higher thermospheric
124 temperatures and CO_2 densities resulting from the storm^{33,34}, similar to decreases inferred during

125 space weather events³⁵. Immediately afterward IUVS showed a 50% brightening at all altitudes,
126 indicating an increase in H abundance resulting from chemical processing of mid-altitude water
127 in the mesosphere and thermosphere. The fact that we are able to observe dimming from the
128 dynamical process before the chemically-driven H increase indicates that thermal effects of the
129 dust event precede chemical effects in influencing the thermosphere. The peak H response occurred
130 nearly one week after water appeared at 60 km, roughly coincident with predictions of simple
131 photochemical models⁹. Based on prior modeling of the optically thick Mars corona^{4,5,36,37}, this
132 50% brightening corresponds to a factor of 5-10 increase in the thermospheric H abundance and
133 a corresponding increase in the H loss rate. Greatly enhanced proton aurora near 150 km in the
134 IUVS observations independently attest to higher H loss, as the brighter aurora are best explained
135 by a denser upstream corona more efficiently converting solar wind protons into energetic neutrals
136 that collide with the thermosphere and emit Lyman alpha light^{38,39}.

137 3 Consequences for Mars Evolution

138 The net result of the Mars Year 34 C-type event was a 5-10-fold increase in H loss across $\sim 20^\circ L_s$
139 (~ 40 sols), reversing the declining seasonal trend (Figure 2). The H loss impact of individual
140 events like this one is comparable to the known annual trend, which peaks in Southern Summer
141 with loss rates at least 20 times higher than those in Southern Winter⁶. While it is likely the mag-
142 nitude of the H loss response to dust events is controlled to some degree by their strength, this
143 response is almost certainly nonlinear on the basis of the available evidence. During the Mars Year
144 28 planet-encircling event, Heavens *et al.*¹⁰ used data from earlier H loss studies^{3,4} which demon-
145 strated a factor of 10-100 decline in the wake of the Mars Year 28 storm, but could not constrain
146 the onset of the storm due to a lack of coronal measurements. The Heavens study also inferred
147 hygropause altitudes and water vapor concentrations at high altitude that are comparable to our
148 measurements using indirect techniques that produce overestimates relative to TGO measurements
149 (see Supplementary Material), indicating that some global events are no more effective at lofting
150 water than regional storms. By contrast, during the Mars Year 34 planet-encircling event, middle
151 atmosphere water abundances retrieved by ACS and NOMAD were 50-100% higher than the abun-
152 dances we report for the regional event^{12,14}, suggesting potentially higher H loss rates during that
153 global event, for which we do not have H loss measurements. Restricting our attention to C-type
154 events only, the Mars Year 34 event was among the strongest 25% of these events well measured
155 from orbit⁴⁰, suggesting that it might have a larger impact on loss than a typical C event. During
156 Mars Year 33, a year with typical dust activity, indirect observations from Halekas⁶ suggest a 50%
157 increase in coronal H inventory coincident with the timing of the C-type dust event, much smaller
158 than the 5-10-fold increase we report here. However, the indirect technique employed by Halekas
159 does not account for variations in atmospheric temperature known to accompany dust events³³.

160 The available data suggests that regional dust events on Mars have a significant and perhaps
161 dominant impact on H escape. Comparing the Mars Year 28 global and the Mars Year 34 C-type
162 event suggests that above a certain strength, dust events have a similar impact on H loss, with
163 each event potentially producing a 50% increase in annual H loss over a hypothetical year with no
164 coronal response. According to Kass *et al.*¹⁶, C-type and A-type dust activity capable of producing
165 a significant northern temperature response due to enhanced interhemispheric circulation occur on
166 average 1-2 times per Mars year, during which high-altitude water transport and H loss is likely to
167 be enhanced across $15 - 40^\circ L_s$ for A-type and $3 - 15^\circ L_s$ for C-type events. B-type events are less

168 likely to drive enhanced loss because their impact is confined to the Southern hemisphere, though
169 this has yet to be definitively established. While planet-encircling events typically last longer than
170 regional events ($45 - 60^\circ L_s$), they occur only about every three Mars years⁴⁰, so that their impact
171 on H loss is likely to be comparable to or smaller than that of A- and C-type regional events, if all
172 such regional events have a similar effect on H loss.

173 Future work should focus on establishing the mechanism for water lofting during dust events
174 using both observations and modeling. While dust heating will certainly increase the altitude of the
175 hygropause, it is not yet clear how water is actually transported to middle and upper atmospheric
176 altitudes. Several proposals exist, including orographic lifting and dusty deep convection⁴¹. Based
177 on the strong H loss response we observe to middle atmospheric water, water transport to the
178 middle atmosphere is likely the limiting step in the H escape chain, rather than the dissociation of
179 water into H and O, the diffusion of H through the thermosphere, or the energization of escaping H
180 atoms. These other processes should all respond roughly linearly to an influx of water from below,
181 as water is optically thin to dissociation on its topside and H is a minor species. In determining
182 the mechanism of water transport, particular emphasis should be brought to bear on understanding
183 any possible mechanistic differences between water lofting at the time of seasonally-strongest
184 circulation strength, during global dust storms, and during regional dust storms. For modeling
185 work, it should be noted that observed dust-driven circulation induced temperature enhancements
186 near the winter pole (~ 40 K for our regional storm and ~ 55 K for the Mars Year 34 global storm⁴²)
187 are typically much larger than models (~ 16 K in Shaposhnikov *et al.*¹¹ and ~ 20 K in Neary *et*
188 *al.*¹³), hinting that models underpredict the circulation strength of the Mars atmosphere during at
189 least some dust events and might therefore also underpredict H loss.

190 Beyond desiccation, regional dust events are a source of oxidizing power to the planet. While
191 all H is lost to space, O can be lost both to space and the Martian crust. Desiccation results from H
192 loss to space no matter the O loss, and oxidation results from more H lost to space than twice the
193 O loss. Our results demonstrate a large enhancement in H loss together with a likely decrease in O
194 loss due to warmer, more collisional thermospheric conditions^{33,43}. Total loss from the atmosphere
195 has to be in the 2:1 stoichiometric ratio of water in a steady state with no species other than H and
196 O escaping and water the only condensable species containing both H and O. With elevated H loss
197 during the storm, more O is left in the atmosphere, which oxidizes the system at least temporarily.
198 Either escape under other conditions is slightly reducing, making up the 2:1 balance over a longer
199 time period, or the O ends up oxidizing the crust. Current estimates of total loss put the H:O escape
200 ratio close to 2:1 on average²; based on our estimated 10x increase in H loss during the event, and
201 assuming no change in O loss (which is driven by the dissociative recombination of the dominant
202 O_2^+ ion and unresponsive to H photochemistry^{44,45}), the ratio of escape in dust events is likely 10:1
203 or larger. This excess indicates that H and O loss should not be taken as balanced on seasonal or
204 interannual timescales (as has been assumed by some studies⁴⁶), but only on the closure timescale
205 of all relevant forcing (the steady-state timescale of Fox & Hać⁴⁷), which may not exist.

206 The time variation of H loss in the geologically recent past is unknown and likely to be
207 strongly affected by the obliquity of Mars, which is variable on timescales longer than 10,000
208 years⁴⁸. At high obliquity, increased interhemispheric circulation could loft more water to high
209 altitude, potentially increasing H loss. At low obliquity, the opposite could occur, with water and
210 CO_2 freezing out at the poles⁴⁹ and a generally weaker general circulation. Because the long-term

211 average obliquity of the planet is higher than the present value, it is likely that H loss measured
212 today is a lower limit on the time-averaged loss rate. Long-term variations in the argument of
213 perihelion would also contribute to a change in the seasonal cycle, though it is likely that the
214 topographic asymmetry of the Northern and Southern hemisphere would result in high altitude
215 water and enhanced H loss in Southern Summer rather than at perihelion⁵⁰.

216 On early Mars, the atmosphere was thick enough to support abundant surface liquid water,
217 and may have been thick enough to limit H loss. In dense atmospheres, the temperature profile is
218 set by greenhouse gas radiative-convective balance, as opposed to the dust-controlled temperature
219 profile of the present-day Mars atmosphere. An early thick atmosphere would likely have had a
220 much more effective cold trap, as is the case today at Earth, strictly limiting the ability of dust to
221 raise atmospheric temperatures and enhance H loss. In addition, the wetter surface would have
222 been less conducive to fine dust formation. This suggests that H loss may have reached a tipping
223 point: as the atmosphere thinned due to other escape processes, it crossed a threshold at which dust
224 events could drive loss. Significant advances in our understanding will be required to determine
225 whether all Mars-sized planets follow a similar trajectory.

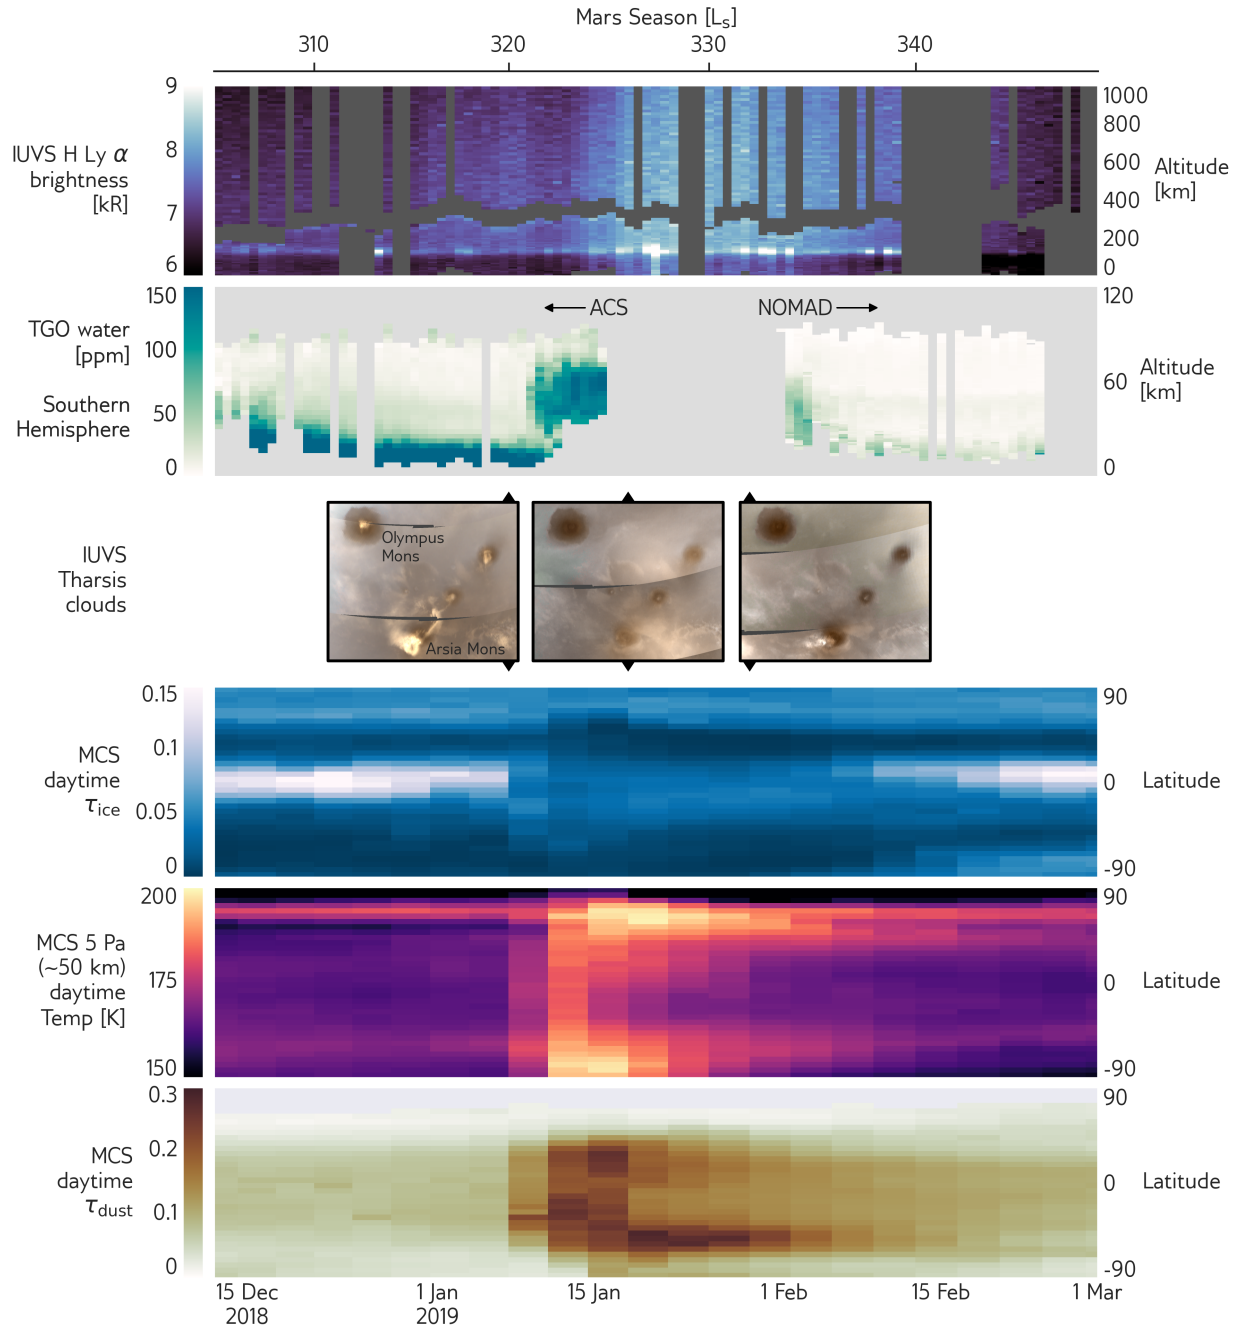

Figure 1: Atmospheric response to the Mars Year 34 C regional dust event. From bottom to top: dust observed by MCS induces a large change in mid-atmosphere temperatures and intensifies interhemispheric circulation, inhibiting ice condensation. IUVS observes equatorial clouds capping the Tharsis volcanoes before and after but not during the event. TGO observes the water that would have condensed into clouds at higher altitudes during the event, peaking ~ 1 week after the beginning of the event. IUVS observes hydrogen increase in brightness by $\sim 50\%$ as a result of this event, consistent with a factor of several increase in H loss. Geometry of the IUVS and TGO observations is provided in the Supplementary Material. Because this event occurred well after southern summer solstice and perihelion, we can conclude that the increase in H loss is controlled by dust dynamics rather than seasonal changes.

The Mars Hydrogen Cycle

Dusty, warm summer atmosphere carries water higher

H_2O

Seasonal vs Impulsive loss

Figure 2: Paradigm for dust-driven and seasonal vs. impulsive escape at Mars. (left) In the traditional scheme, H loss is regulated by the slow-and-steady diffusion of molecular hydrogen to the upper atmosphere, with minimal changes in the loss rate with season or lower atmospheric conditions. In the emerging paradigm for H loss, seasonal or impulsive changes in dust can loft water to high altitude where it can directly boost escape. (top right) H loss from Mars peaks in Southern Summer because of seasonal changes associated with the solstice and perihelion, increased interhemispheric circulation, greater average dust activity, and greater insolation. (bottom right) For this work, we are able to distinguish impulsive loss due to the C-type dust event from seasonal loss because this event and its associated H loss enhancement occurred in the declining phase of the known seasonal trend. Determining the conditions under which impulsive H loss dominates seasonal or quiescent loss should be a focus of ongoing and future studies.

251 **Author Contributions** M.S. Chaffin oversaw the study and cross-instrument comparison, and performed
252 MAVEN IUVS H data analysis. D.M. Kass along with N.G. Heavens and A. Kleinböhl performed MCS data
253 analysis. S. Aoki analyzed the NOMAD data. I.R. Thomas and J.T. Erwin calibrated the NOMAD data and
254 planned NOMAD observations, assisted by B. Ristic. F. Daerden helped assess the scientific relevance of
255 NOMAD detections. A.C. Vandaele, M. Patel, G. Bellucci and J.J. Lopez-Moreno supervised the scientific
256 observations of NOMAD. A.A. Fedorova performed the TGO/ACS data analysis. J. Deighan identified the
257 event in the IUVS data and suggested followup. K. Connour provided IUVS apoapsis images of clouds.
258 All authors made significant contributions to understanding or operating the instruments for which data are
259 presented and participated in the preparation of the manuscript text.

Supplementary Material

1 Observation Geometry

While the Mars Reconnaissance Orbiter and Trace Gas orbiter mission are in relatively stable orbits designed for consistent remote sensing, MAVEN's orbit precesses with time to facilitate broad sampling of the atmosphere with its suite of in-situ instruments. This limits the availability of coronal observations useful for constraining H loss with IUVS.

Coronal observations are made on the outbound and inbound segments of MAVEN's elliptical orbit, when H Lyman alpha can be observed at high altitude. These observations can be used to constrain H loss when MAVEN's apoapsis is on the dayside at relatively low latitude. As shown in Figure 3, this configuration has occurred only rarely over the course of the MAVEN mission, most notably during the MY34 C storm that we report on here. Earlier occurrences of this observation geometry did not have corresponding TGO data.

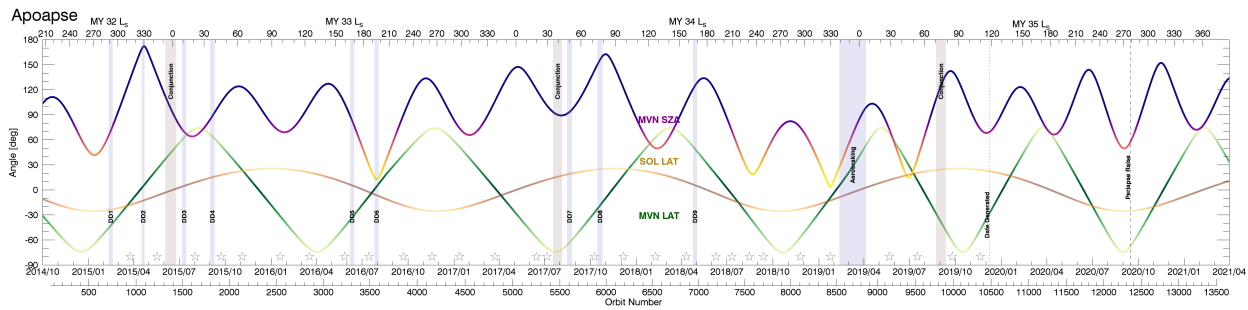

Figure 3: Geometry of MAVEN apoapsis location throughout the MAVEN mission. MAVEN orbit numbers and Earth Year/Month dates are shown on the bottom axis, with Mars Year and L_s on the top axis. The purple/pink and green curves show the location of MAVEN's apoapsis in solar zenith angle (SZA) and geographic latitude, respectively. The tan curve shows the latitude of the subsolar point. Intermittent spacecraft activities such as MAVEN Deep Dips (DD-X), Earth-Sun-Mars conjunctions, and the recent aerobraking campaigns are also indicated. IUVS Stellar occultation campaigns are indicated with the star icons. Time periods useful for IUVS H loss measurements occur when apoapsis SZA and latitude are both close to zero and occur relatively rarely in the dataset.

Zooming in on the time period presenting in the paper, Figure 4 shows the geometry of the TGO and MAVEN observations during the study period of the Mars Year 34 C storm. The regularity of the MRO/MCS observations obviates the need for visualization, as these observations occur at 3PM across all latitudes and have been zonally averaged across all longitudes.

2 MCS Data Processing

MCS (Mars Climate Sounder) has 9 spectral channels from 0.3 to $45 \mu\text{m}^1$. MCS measures limb (or horizon) radiances from the surface to $\sim 90 \text{ km}$ with $\sim 5 \text{ km}$ vertical resolution provided by arrays of 21 detectors for each channel and acquires on-planet observations. MCS is on MRO (Mars Reconnaissance Orbiter) and observes the atmosphere at $\sim 3 \text{ pm}$ (daytime) and $\sim 3 \text{ am}$ (nighttime) globally on a daily basis². Geophysical profiles of temperature, dust opacity (at $22 \mu\text{m}$), and water ice (at $12 \mu\text{m}$) as well as surface brightness temperature are retrieved from the radiances using a 2-D radiative transfer code³⁻⁵. (The MCS opacities can be converted to visible opacities with a

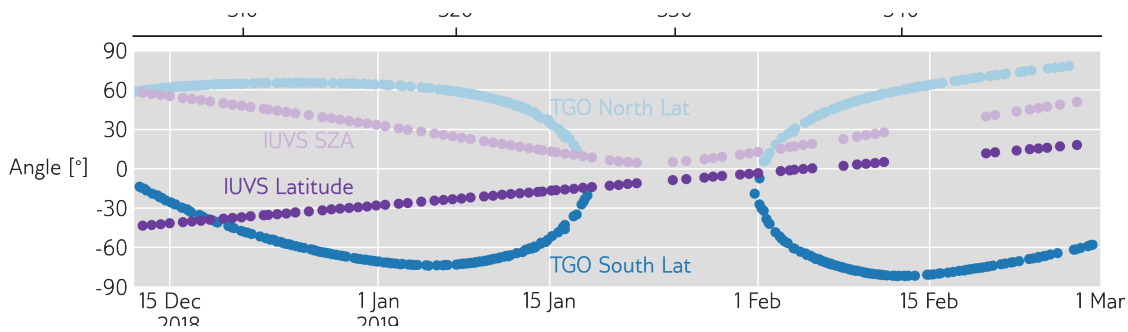

Figure 4: Geometry of TGO and IUVS observations shown in Figure 1. Points show the Mars surface geometry of the point along the observation line of sight with minimum ray height. For TGO, occultations are made in both hemispheres, but Figure 1 shows only Southern Hemisphere data. MCS observations are made at 3 PM across all latitudes, and zonally averaged across longitudes, and so are not shown here. Both TGO and IUVS observing geometry evolved with time over the period of the study, with minimal impact on the conclusion that regional storms can make possible large amounts of high-altitude water that subsequently increases coronal H abundances and loss rates.

450 multiplying factor of 7.3 for dust and 3.3 for water ice⁴). The specific retrievals used in this work
 451 are optimized for the retrieval of dust opacity profiles under major dust storm conditions⁶. The
 452 aerosol opacity profiles are integrated (after being extended will mixed to the surface for dust) to
 453 obtain the column opacities used in this work.

454 The individual retrieved profiles are then used to calculate a zonal mean value through bin-
 455 ning (bin size is 5° in latitude by 2° in Ls) to match the MCS coverage patterns⁷. This was per-
 456 formed for the temperatures on the 5 Pa pressure surface (~ 50 km above the surface) as well as
 457 the dust and ice column values. The dust column opacity values were filtered to removed CO₂ ice.

458 3 NOMAD Data Processing

459 The vertical profiles of water vapor volume mixing retrieved by the NOMAD SO data shown in
 460 this study were presented in Aoki *et al.*⁸. Here, a brief summary of the retrieval method is de-
 461 scribed. The NOMAD spectra in the diffraction order 134 (3011-3035 cm⁻¹) and 168 (3775-3805
 462 cm⁻¹), that includes strong H₂O lines, were processed. The retrievals were performed with the
 463 ASIMUT-ALVL radiative transfer and inversion code⁹. H₂O, and CO₂ molecules absorption were
 464 taken into account in the radiative transfer calculation and the absorption coefficients were cal-
 465 culated using the following spectroscopic database: HITRAN 2016 database¹⁰ for CO₂, and the
 466 water line list for CO₂-rich atmospheres by Gamache *et al.*¹¹ for H₂O. The temperature, pressure,
 467 and CO₂ volume mixing ratio of the simulated atmosphere was obtained from the Global Envi-
 468 ronmental Multiscale Mars model (GEM-Mars)¹² which takes into account the effects of the dust
 469 storms in MY34¹³. The retrievals were performed using the Optimal Estimation Method (OEM)¹⁴
 470 for each spectrum at each tangential altitude independently. The retrieved abundances from each
 471 diffraction order were finally averaged with an interval of 1 km to obtain the vertical profiles. A
 472 complete datasets retrieved from the NOMAD measurements are available on the BIRA-IASB data
 473 repository: <http://repository.aeronomie.be/?doi=10.18758/71021054>.

4 ACS Data Processing

The procedure to obtain the water mixing ratio profiles from the occultation data is described by Fedorova *et al.*¹⁵. The CO₂ and H₂O abundances from respectively the 1.57 and 1.38 μm spectral regions are measured in parallel with a slight altitude shift due to sequential measurements of the diffraction orders, which is accounted for using interpolation. A forward model of transmission is computed using a look-up-table of absorption cross-sections (as a function of pressure and temperature) for a corresponding number of atmospheric layers (40 to 130 depending on orbit), using the spectral line parameters from the HITRAN 2016 database¹⁰ with a correction coefficient of 1.7 for the H₂O broadening in CO₂-dominated atmosphere and self-broadening in the case of CO₂.

To get temperature and pressure, the model fitting is performed on the data of the diffraction order 49 (6318 – 6387 cm⁻¹), which covers a CO₂ absorption band, including multiple temperature sensitive lines with different groundstate energy (E''). We use a Levenberg-Marquardt iterative scheme¹⁴ and Tikhonov regularization to smooth the profile and minimize the uncertainties^{16,17}. The hydrostatic equilibrium was taken into account to constrain simultaneous retrieval of temperature and pressure¹⁵. The initial temperature, pressure and CO₂ volume mixing ratio profiles were taken from the Martian Climate Database MCD 5.3 profiles¹⁸. The retrieval algorithm converges within 4-6 iterations independently of initial assumptions. The H₂O number density and VMR are retrieved applying a similar retrieval procedure to the spectra in the diffraction order 56 (7217 – 7302 cm⁻¹ encompassing the 1.38-μm water vapor band. Only one free parameter vector is retrieved (the H₂O VMR) with the pressure and temperature profile from order 49. The uncertainty on the retrieved quantities is given by the covariance matrix of the solution. We also account for the Jacobian errors due to the retrieved T and P. For water vapor, the retrieval accuracy sharply depends on the aerosol loading, and, for a clear atmosphere (with an optical depth 0.2), remains better than 1 ppmv at 10-50 km.

5 IUVS Data Processing

Data reduction procedures for H Lyman alpha data are identical to those described in Chaffin *et al.*¹⁹. We present outlimb and outcorona data available on the PDS Atmospheres Node, Version 13, Revision 01. For the outlimb data presented, we use only the last outlimb scan, which underlies the outcorona scan. The Lyman alpha brightness observed by MAVEN is a function of the H abundance and the solar brightness, which we correct for using the MAVEN-measured brightness of the Sun²⁰. Because Mars H Lyman alpha is optically thick, some of the variation we observe is also due to the viewing geometry. These observations occurred as MAVEN's orbit apoapsis was slowly evolving in the vicinity of the subsolar point, minimizing geometrical effects.

507 **6 Comparison of Water Retrievals from TGO and MCS**

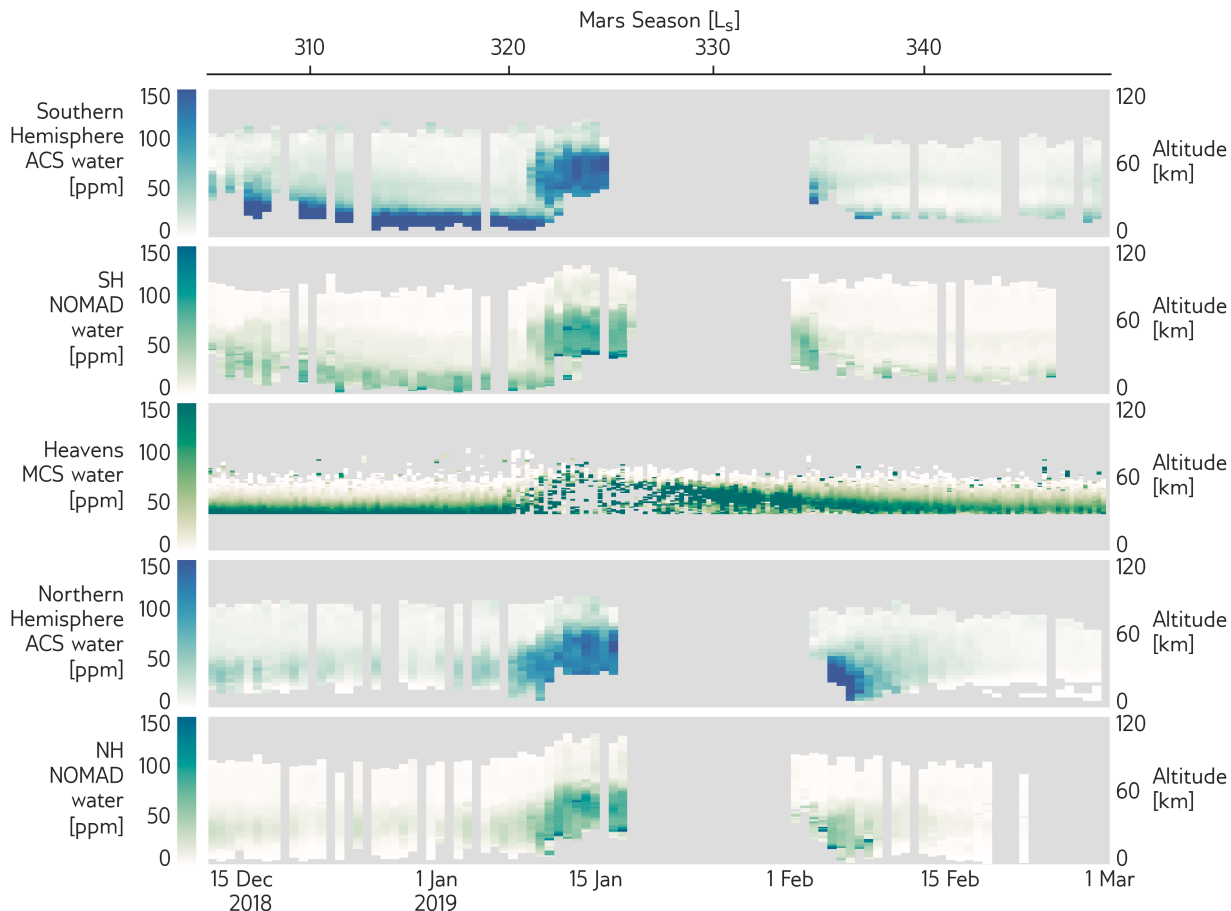

Figure 5: Comparison of middle atmosphere water retrievals. From top to bottom, water retrieved in the Northern Hemisphere by ACS and NOMAD; MCS water retrievals using the methods of Heavens *et al.*²¹; and Southern Hemisphere water retrievals from ACS and NOMAD. Data presented in the text comes from the Southern Hemisphere, from ACS before L_s 330, and from NOMAD afterward. Color scales are unique to each instrument for clarity, but because these schemes are perceptual the perceived darkness in each panel is a trustworthy indicator of the water abundance retrieved. ACS retrieved abundances are higher than NOMAD abundances and display larger variations; MCS retrievals are higher than both and limited in altitude range.

508 A comparison of water retrievals during the event is shown in Figure 5. In the text we present
 509 Southern Hemisphere retrievals from both TGO instruments, selecting ACS before L_s 330 and NO-
 510 MAD thereafter. Both instruments show the same overall variations, with ACS retrieving more
 511 water near the surface and at altitude during the dust event than NOMAD. NOMAD retrievals extend
 512 closer to the gap in observations than ACS, permitting detection of high altitude water in the
 513 declining phase of the storm near L_s 335. Water estimates retrieved from MCS data using assumed
 514 saturation conditions are mostly higher than the more direct measurements of ACS and NOMAD,
 515 suggesting either that water was not saturated in the regions where MCS retrievals were possible,
 516 or that fast diurnal variation in high-altitude water is required to explain the discrepancy between

517 the datasets. Near the peak of the event the absence of clouds on which the MCS retrieval depends
518 introduces noise into this retrieval.
