1. Experimental and analytical methods

1.1. Starting material

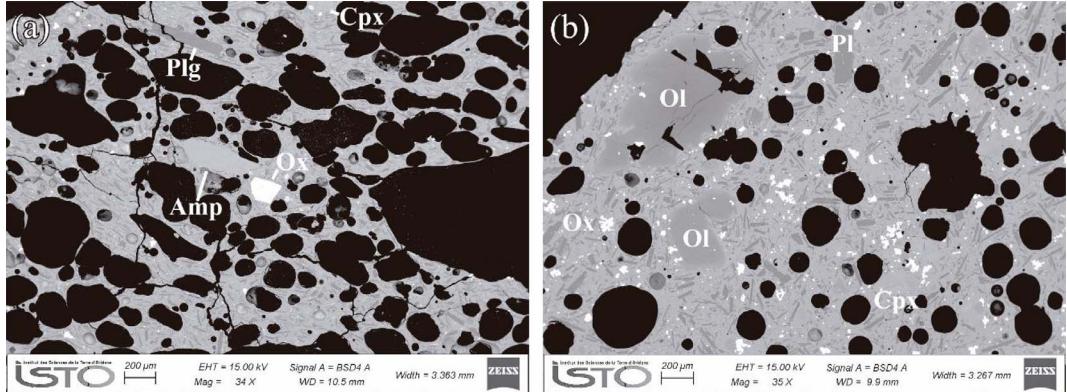

Experiments were performed on two natural compositions from historical eruptions of Tenerife (Canary Islands, Spain): a basanite scoria from the north-eastern vent of Fasnia volcano [1705 A.D.; Albert et al., 2015] and a phonotephrite from the scoria cone of Garachico volcano [1706 A.D.; Carracedo and Perez-Torrado, 2013; Solana, 2012] (Figure 1).

The natural samples were prepared by crushing and milling scoria fragments, which were finely ground under ethanol using an agate mortar. In order to obtain homogeneous and nominally anhydrous

glasses, the resulting powder was held in a Pt crucible for a two-step fusion (with grounding in between) at 1400 °C during 4 h in open-air atmosphere and rapidly quenched in a water container at room temperature. The composition of the starting materials was analysed by electron microprobe (EPMA, Table 1) to ensure that no significant compositional variation (i.e., Na or Fe loss toward the crucible) occurred during the melting process. The resulting glass compositions tightly agree (within errors) with X-ray fluorescence analysis performed independently on the samples (Table 1).

Although Garachico rock lies on the basanite-phonotephrite boundary (Figure 1b) in the total alkalis versus silica classification [TAS, Le Bas et al., 1986], its mineral assemblage corresponds to that of a phonotephrite from Tenerife [Ablay et al., 1998],

* Corresponding author.

Supplementary Figure S1. Back-scattered electron images of the scoriae samples, showing (a) a general view of Garachico phonotephrite with clinopyroxene (Cpx), amphibole (Amp), plagioclase (Pl) and Fe–Ti magnetite (Ox) microphenocrysts. (b) A general view of Fasnía basanite with olivine (Ol) and clinopyroxene (Cpx) phenocrysts, plagioclase (Pl) and Fe–Ti magnetite (Ox) microphenocrysts.

with <5 wt.% of clinopyroxene, Ca-rich amphibole (kaersutite), Fe–Ti magnetite and plagioclase phenocrysts. The same phases plus Fe–Ti oxides and apatite are present as microphenocrysts (<0.15 mm) in a fine-grained glassy and vesiculated groundmass (Figure S1a). In comparison, the phenocrysts of Fasnía basanite are dominated by olivine, clinopyroxene and Fe–Ti magnetite [13 wt.%; Albert *et al.*, 2015]. These phases, along with plagioclase, are also present as microphenocrysts in the glassy vesiculated groundmass of the scoriae (Figure S1b).

1.2. Capsule preparation

H_2O -saturated and CO_2 -saturated charges were prepared separately using 2–2.5 cm long, 2.5 mm inner diameter and 0.2 mm wall thickness Au80–Pd20 capsules, which minimize iron loss during experiments under reduced conditions [Di Carlo *et al.*, 2006]. Each capsule was prepared as follows: one end of the capsule was initially arc-welded and different amounts of the gas-source materials (H_2O or CO_2 see below) were first added into the capsules. For the set of H_2O solubility experiments, 3.5–8 μL of deionized water was added via a microsyringe, whereas for CO_2 solubility runs, silver oxalate ($\text{Ag}_2\text{C}_2\text{O}_4$) was used (3–9 mg): upon heating, this compound decomposes into metallic silver and pure CO_2 gas phase. After volatiles, glass chips <2 mm were loaded into the capsules in amounts (typically 60–80 mg) ensuring that fluid-saturated conditions were always achieved

[e.g., Andújar and Scaillet, 2012b; Scaillet *et al.*, 1995] (Table 2).

All capsules were weighed before and after adding each component and finally sealed by electric arc welding of the top end. After this step, if no significant loss occurred (difference <0.0004 g), they were left in an oven for several hours (~24 h) at 120 °C to ensure homogeneous fluid distribution and then weighed again. After the experiments, capsules were re-weighed to guarantee that no volatile loss had occurred and pierced for opening with cutting pliers. For H_2O experiments, the spur and/or the presence of small water bubbles hissing out from the capsules when opening confirmed that water-saturated conditions were attained.

1.3. Experimental equipment and procedures

A total set of 18 solubility experiments were conducted at the ISTO laboratory (Orléans, France) in internally heated pressure vessels (IHPV) operating vertically, using pure argon or a Ar– H_2 gas mixture at room temperature as the pressure medium to achieve the desired $f\text{O}_2$ (see below).

Experiments were carried out at 1200 °C and pressures from 50 to 400 MPa (Table 2). The run duration was between 4 and 6 h, long enough to attain melt–fluid phase equilibrium under these conditions and to minimize iron-loss towards the capsule. Previous experimental studies on water and carbon diffusivities [e.g., Behrens and Zhang, 2001; Behrens *et al.*,

2004; Zhang *et al.*, 1991], and redox reaction kinetics in silicate melts [Berndt *et al.*, 2002; Gaillard *et al.*, 2002; 2003a, 2003b] have shown that few hours (1–1.5 h) are sufficient to achieve the equilibrium between the melt and the fluid phase at these P–T conditions, especially in mafic to intermediate compositions [Behrens *et al.*, 2009; Botcharnikov *et al.*, 2005, 2006; Dixon *et al.*, 1995; Lesne *et al.*, 2011a, 2011b].

A typical run consisted of two capsules (one loaded with H₂O and the other with CO₂), wrapped in Pt cages and suspended by a Pt or Rh quench wire to the rapid-quench device. Heating was applied by a double-winding molybdenum furnace, which ensures a 3 cm long near-isothermal zone [$\pm 2\text{--}3\text{ }^{\circ}\text{C}\cdot\text{cm}^{-1}$; Andújar *et al.*, 2013] where the capsules are placed. The temperature was measured using two S-type thermocouples (accuracy of $\pm 5\text{ }^{\circ}\text{C}$) located on both the upper and lower parts of the T-homogeneous zone, allowing precise control of thermal gradients. The total pressure was recorded continuously by a transducer calibrated against a Heise Bourdon gauge with an uncertainty of $\pm 2\text{ MPa}$ [e.g., Di Carlo *et al.*, 2006; Pichavant *et al.*, 2009]. Experiments were ended using a rapid-quench technique with which the sample holder falls into the bottom part of the vessel and experiences isobaric quench at cooling rates $>100\text{ }^{\circ}\text{C/s}$ [Di Carlo *et al.*, 2006]. All the experiments reported here showed a fast transient increase in total pressure of 10–40 bars upon the falling of the capsules, indicating that the drop quench was successful in each case.

It should be noted that in high pressure and H₂O-rich charges, quench crystals of 1–2 μm were observed (see Table 2). Similarly, under oxidising conditions (NNO + 3.2, see below), some basanitic and, to a lesser extent, phonotephritic, experimental glasses contained scarce amounts of Fe–Ti oxides (<7 wt.% as estimated from least-square mass-balance calculations; Table 2), which did not prevent, however, the acquisition of FTIR, EPMA and NanoSIMS data. Only charge F4b with $X_{\text{H}_2\text{O}} = 1$ and performed at 400 MPa (Table 2) contains slightly higher amounts of randomly distributed needle-shaped quench crystal aggregates that prevented the FTIR analysis from being performed. Consequently, for this charge, the glass water content was measured by the elemental analyzer and used, along with FTIR results, to complete the basanitic H₂O solubility dataset. Scarce microbubbles (<5–10 μm) to larger

bubbles (0.3–0.5 mm) are located at the melt/capsule interface, mainly in CO₂ experiments, confirming that fluid saturation at given P and T was attained.

1.4. Redox conditions of the experiments

The effect of $f\text{O}_2$ on H₂O and CO₂ solubilities was explored by imposing two different oxygen fugacities in our experiments. The first set was pressurized with pure Ar, which corresponds to a $f\text{O}_2 \sim \text{NNO} + 3.2$ (± 0.1 log unit), where NNO is the nickel-nickel oxide buffer at the relevant P–T [Huebner and Sato, 1970]. The low amounts of quench phases are inconsequential to the interpretation of solubility trends. In all cases, the $f\text{O}_2$ of H₂O-bearing capsules is controlled by the fugacities of H₂ and H₂O through the reaction $\text{H}_2 + (1/2)\text{O}_2 \leftrightarrow \text{H}_2\text{O}$. Hence, to compute $f\text{O}_2$ in oxidizing experiments, we used the prevailing intrinsic $f\text{H}_2$ in the vessel (known from previous experiments performed in the same IHPV apparatus under similar P–T– $f\text{H}_2$ conditions [run 22 and run 23, Pichavant *et al.*, 2009], the dissociation constant of water [from Robie *et al.*, 1979], and the fugacity of pure water at the experimental P–T conditions [Burnham *et al.*, 1969]. For CO₂-bearing charges, the $f\text{O}_2$ was determined considering the calculated $f\text{H}_2\text{O}$ from the amount of dissolved water measured in each experimental product at any given P–T conditions (see below). A second set of experiments was performed under moderately reduced $f\text{O}_2$ conditions, which were obtained by pressurizing the vessel with an argon–hydrogen gas mixture equivalent to 1.5 bar H₂ of the total gas volume. For these runs, the prevailing $f\text{H}_2$ was independently determined using Ni–Pd–O solid sensors via two additional experiments run at 200 and 400 MPa at 1200 °C with the same H₂/Ar proportion but of longer duration (22–24 h). Sensors consisted of two pellets of Ni–Pd metal mixtures (each one with different Ni/Pd ratios) plus ZrO₂ as isolating material, placed in Au80–Pd20 capsules in the presence of excess H₂O following the procedure of Taylor *et al.* [1992]. The composition of the NiPd alloy was determined by electron microprobe analysis after the experiment, allowing $f\text{O}_2$ calculation of the sensor system from Pownceby and O'Neill's [1994] equation. Afterward, once the prevailing $f\text{O}_2$ is known, the $f\text{H}_2$ and the $f\text{O}_2$ of each charge was calculated as stated above. For the moderately reduced experiments, the oxygen fugacity was calculated to be $\sim\text{NNO} + 1.4$

(± 0.2 log unit). All experiments are reported in Tables 2 and 3.

Since the oxygen fugacity in capsules in H₂O-bearing systems is related to the fugacity of H₂ and H₂O through the water equilibrium reaction (H₂ + (1/2)O₂ ↔ H₂O), a decrease in *f*H₂O (or *a*H₂O) at constant *f*H₂ (the one prevailing in the vessel) is accompanied by a decrease in *f*O₂ [e.g., Scaillet *et al.*, 1995; Webster *et al.*, 1987]. It should be noted that, even if the CO₂ experiments were performed under nominally dry conditions (no H₂O added), they are not strictly water-free, as evidenced by the low amounts of water analysed in our experimental glasses (see below). Therefore, the *f*O₂ of CO₂-bearing charges was calculated using the *f*H₂O retrieved from our empirical equation relating *f*H₂O and melt water content, and the prevailing *f*H₂, as determined above. The calculated oxygen fugacity of CO₂-bearing experiments decreases by 1 to 3 log units relative to H₂O saturated conditions, depending on melt water content, as observed in other experimental studies [e.g., Behrens *et al.*, 2009; Botcharnikov *et al.*, 2005; Lesne *et al.*, 2011a, 2011b; Webster *et al.*, 1987; Table 2].

1.5. Analytical methods

1.5.1. Major element compositions

Starting materials and run products were mounted in epoxy resin, polished and analysed with a Cameca SX-Five electron microprobe at ISTO-BRGM (Orléans, France) (Table 1 and S1). Analytical conditions were: 15 kV accelerating voltage, beam current of 6 nA, counting times of 10 s and a defocused 20 µm beam diameter to minimize alkali migration [i.e., Andújar and Scaillet, 2012b; Morgan and London, 2005]. Sodium and potassium were analysed first to limit any loss and a Phi-Rho-Z correction procedure was applied. Major elements calibration has been performed using standards of (1) silicate minerals: albite (Na, Si), orthoclase (K), andradite (Ca) topaz (F); (2) phosphates: apatite (P), vanadinite (Cl); sulphates: baryte (S); and (3) oxides: chromite (Cr), corundum (Al), magnesium oxide (Mg), nickel oxide (Ni), hematite (Fe) and pyrophanite (Mn, Ti). For the oxides, the relative analytical errors are 1% (SiO₂, Al₂O₃, CaO), 3% (FeO, MgO, TiO₂) and 5% (MnO, Na₂O, K₂O, P₂O₅) [Di Carlo *et al.*, 2006].

Metallic sensor phases were analysed under an accelerating voltage of 15 kV and a sample current of 20 nA, using pyrite, nickel, palladium and platinum as standards.

1.5.2. Density

The density of quenched glasses was measured using Archimedes' method in a Mettler Toledo AG balance equipped with a density accessory kit. Archimedes' principle states that a body immersed partially or fully in fluid experiences a buoyant force acting upwards on it, so the magnitude of this force is equivalent to the weight of the fluid displaced by the body. Thus, samples were weighed in air and then in absolute ethanol at a known atmospheric temperature, using the following equation to calculate the density:

$$\rho = A / ((A - B) * (\rho_0 - \rho_L) + \rho_L) \quad (S.1)$$

where *A* is the weight in air, *B* is the weight in ethanol, ρ_0 is the density of ethanol and ρ_L is the density of air. The measurements were repeated 10 to 12 times on samples weighing from 5 up to 58 mg. Density measurements vary from 2626 to 2787 g/l for the basanite and from 2523 to 2669 g/l for the phonotephrite (Table 2). Analytical errors remain below 2.5% for most experimental glasses, reaching values between 3.1 and 4.8% in cases where large glass fragments were not available (<10–15 mg).

1.5.3. Fourier transform infrared spectroscopy

H₂O and CO₂ contents in experimental glasses were measured by FTIR spectroscopy (Table 2) on doubly polished glass chips with different thicknesses, ranging from 15 to 200 µm. The thickness at each analysis point was measured at least three times with a LEITZ DMR optical microscope equipped with an automated X-Y stage, enabling measurements within 2 µm. FTIR spectra were collected in transmission using a Nicolet 6700 FTIR spectrometer attached to an IR microscope (Nicolet Continuum) equipped with a MCT detector at the ISTO-CNRS laboratory. A Globar light source, a XT-KBr beamsplitter and a 32x infinity-corrected Schwarzschild objective matching to 32x condenser were used to record absorbances of the fundamental OH-stretching vibration (~ 3520 cm⁻¹) and the carbonate doublet (~ 1430 cm⁻¹ and ~ 1520 cm⁻¹) in the mid-infrared (MIR) region, as well as combination bands of molecular water

^a Total iron expressed as FeO.

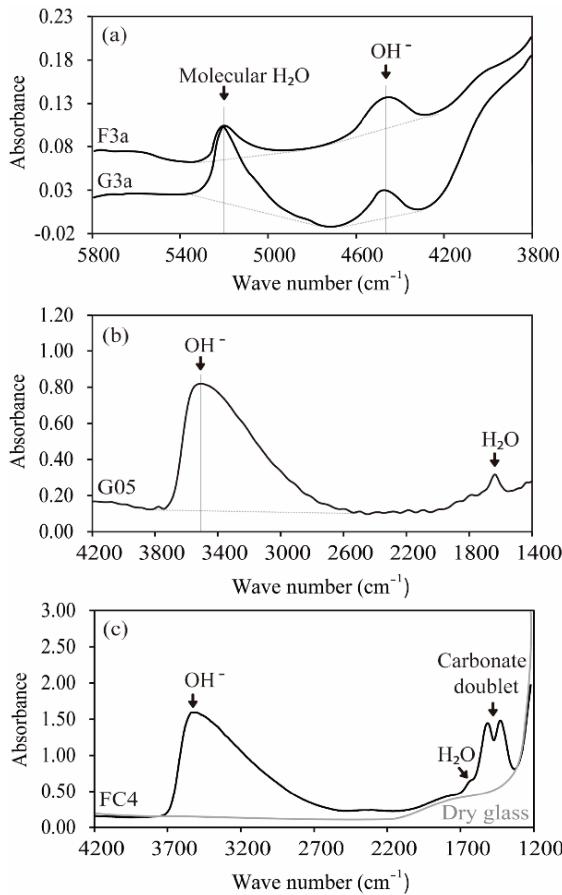

(5200 cm⁻¹) and hydroxyl groups (4500 cm⁻¹) in the near-infrared (NIR) region (Table S3). For each analysis, 128 scans were collected in the range of 6000 to 655 cm⁻¹ with an aperture of 50 × 50 µm and a spectral resolution of 4 cm⁻¹, collecting a background on CaF₂ (for H₂O) and NaCl (for CO₂) windows before each sample. Typically, three to seven spots were acquired in different parts of the glass chips to ensure the homogeneous distribution of the volatile phases over the samples and the results were then averaged.

The concentration of H₂O and CO₂ were determined using the Lambert-Beer law:

$$C_i = (M_i * A_j) / (\rho * d * \epsilon_j) * 100 \quad (S.2)$$

where C_i is the concentration of species i (in wt.%), M_i is the molecular weight of the species i , A_j is the absorbance (peak height of band j), ρ is the density of the run product (in g/L, see above), d is the thickness of the glass chip at each analysed point (in cm) and ϵ_j is the absorption coefficient of band j (in L/mol·cm).

For NIR and MIR water spectra, two tangents [TT baseline, Lesne et al., 2011a, 2011b; Ohlhorst et al., 2001; Schanofski et al., 2019] were applied to the base of the 4500 cm⁻¹, 5200 cm⁻¹ and 3520 cm⁻¹ bands to measure the peak heights (see Figure S2a, b). In the case of carbonate doublet, before the TT baseline

Supplementary Figure S2. Near-IR and Mid-IR representative spectra of different basanitic and phonotephritic experimental glasses. Bold lines represent measured spectra and grey lines the fitted baselines. (a) Molecular water band at 5200 cm^{-1} and the hydroxyl band at 4500 cm^{-1} of the F3a (6.14 wt.% H₂O) and G3a (6.32 wt.% H₂O) samples. (b) The absorbance of the fundamental OH- stretching vibration at about 3520 cm^{-1} of the G05 glass (2.35 wt.% H₂O). (c) The spectrum of the corresponding starting dry glass (thick grey line), scaled to the same thickness, was used for subtracting from the sample spectrum (FC4, 5748 ppm CO₂) to measure the peak heights of the carbonate peaks at 1430 cm^{-1} and 1520 cm^{-1} .

correction, a subtraction from volatile-free glasses with the same composition and normalized to the same thicknesses was applied (Figure S2c).

The lack of bulk H₂O and CO₂ data prevented us from determining molar absorption coefficients for the compositions studied here. To contour this limitation, we used absorption coefficients derived from magma compositions that closely approach those studied here. For the Fasnía basanite, water contents were quantified using the following absorption coefficients $0.56 \pm 0.04\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$ and 0.58

$\pm 0.02\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$ for ε_{5200} and ε_{4500} , respectively [Cocheo, 1993], and $59.2 \pm 4\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$ for ε_{3520} [Shishkina *et al.*, 2014]; whereas for the Garachico phonotephrite $1.02 \pm 0.03\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$, $0.62 \pm 0.06\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$ and $63.9 \pm 5.4\text{ L}\cdot\text{mol}^{-1}\text{ cm}^{-1}$ we used for ε_{5200} , ε_{4500} and ε_{3520} , respectively [Behrens *et al.*, 2009].

Despite that no water was added to the CO₂-solubility charges, our FTIR spectra show that all run products contained small amounts of dissolved water (≤ 2 wt%; Table 2; Figure S2c). For this reason,

the carbonate band at 1520 cm^{-1} was slight to moderately affected by the H_2O bending at 1630 cm^{-1} and could not be used for CO_2 quantification purposes [e.g., Behrens *et al.*, 2009; Botcharnikov *et al.*, 2006; Shishkina *et al.*, 2014]. Therefore, we used the 1430 cm^{-1} peak to calculate the dissolved CO_2 in all experimental glasses considering the absorption coefficients of $283 \pm 8\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$ for Fasnia basanite [Dixon and Pan, 1995] and $264 \pm 15\text{ L}\cdot\text{mol}^{-1}\cdot\text{cm}^{-1}$ for Garachico phonotephrite [Vetere *et al.*, 2014].

Considering the strong dependence of the absorption coefficient with composition, the major source of error associated with our FTIR $\text{H}_2\text{O}-\text{CO}_2$ quantifications comes from the use of coefficient values that have not been specifically calibrated for our magmas [e.g., Dixon and Pan, 1995; Dixon *et al.*, 1995; Mandeville *et al.*, 2002]. Notwithstanding, the errors associated with the volatile-content quantification were calculated by propagating errors associated to absorbance, density, absorption coefficient, and thickness. Calculated errors are about 5–15%, i.e., similar to those of previous studies [Behrens *et al.*, 2009; Iacono-Marziano *et al.*, 2012; Lesne *et al.*, 2011a, 2011b; Shishkina *et al.*, 2014].

As in previous studies [e.g., Allison *et al.*, 2019; von Aulock *et al.*, 2014], we observed a good correlation between peaks height and water concentration in the glass, since the difference between contents determined using the $\sim 3500\text{ cm}^{-1}$ peak and those from near-IR data is usually $<0.15\text{ wt.\%}$ (Table 2). However, for data discussion and further comparison, we preferred to use here the results from the combination of the molecular water (5200 cm^{-1}) and hydroxyl groups (4500 cm^{-1}) bands, as their propagated errors are less than 10% compared to those associated with the fundamental band (15%). Such a difference (5%) arises from the necessity of using relatively thin glass wafers (i.e., $15\text{--}40\text{ }\mu\text{m}$ thickness) to ensure (1) a good proportionality between peak heights and water contents and (2) avoiding peak-detector saturation. However, despite this technical advantage, the accuracy of $\pm 2\text{ }\mu\text{m}$ in the thickness measurement propagates into higher relative errors when using relatively thin wafers for determining melt water concentrations.

1.5.4. Nanoscale secondary ion mass spectrometry

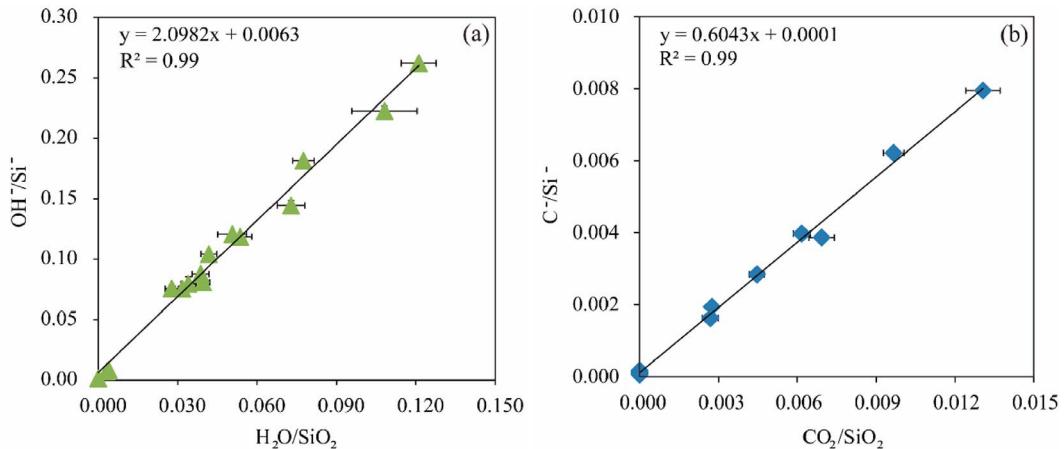

Experimental glasses were also analysed using the Cameca NanoSIMS 50 installed at the Muséum

National d'Histoire Naturelle in Paris with the aim of verifying the suitability of the selected absorption coefficients to retrieve H_2O and CO_2 contents from our experimental glasses. We could apply this procedure since the NanoSIMS independently measures the OH/Si and C/Si ratios of the sample so that if the entered values of H_2O and CO_2 do not match with the measured ratios, a calibration regression line cannot be established. For this reason, we used our H_2O and CO_2 experimental glasses as NanoSIMS secondary standards obtaining, in this case, a good regression of the data (as evidenced by the $R^2 = 0.99$; Figure S3), which validates our previous choice concerning the absorption coefficients for both compositions to determine H_2O and CO_2 contents using FTIR.

NanoSIMS analyses were performed using a 19 pA Cs^+ primary beam rastered over $3 \times 3\text{ }\mu\text{m}^2$ surface area. However, to avoid surface contamination, only ions from the inner $1.5 \times 1.5\text{ }\mu\text{m}^2$ were collected using the “beam blanking” mode. Secondary ions of $^{12}\text{C}^-$, $^{16}\text{OH}^-$ and $^{28}\text{Si}^-$ were recovered in multicollection mode. Mass resolving power was set at a minimum of 5600, a value which is sufficient to resolve interferences on $^{16}\text{OH}^-$. A single analysis comprises a stack of 100 cycles, each lasting for 1.024 s. An electron flooding gun was used for charge compensation. Prior to each analysis, a 235 pA Cs^+ primary beam was used for presputtering over $5 \times 5\text{ }\mu\text{m}^2$ surface area for 2 min to remove surface contamination and reach a steady-state sputtering [Thomen *et al.*, 2014]. The vacuum in the analysis chamber remained below $2 \times 10^{-10}\text{ Torr}$ during measurements. Once optimal analytical conditions were achieved, the H_2O and CO_2 contents of the experimental glasses were determined through the measurement of $^{16}\text{OH}^-/^{28}\text{Si}^-$ and $^{12}\text{C}^-/^{28}\text{Si}^-$ ratios, respectively. Concentrations and uncertainties were determined using the R program following the procedure described in Bartoli *et al.* [2014] and Thomen *et al.* [2014].

1.5.5. Elemental analyzer

As we pointed out in previous sections, despite the systematic use of the rapid-quench device in our experiments, one charge (F4b, Table 2) presented quench mineral phases in proportions and with distributions that did not allow direct measurements with FTIR or NanoSIMS. Therefore, we determined the bulk H_2O -content of 9 run products with a

Supplementary Figure S3. NanoSIMS calibration curves. (a) Correlation between the measured OH⁻/Si⁻ ratio by the NanoSIMS vs. the H₂O/SiO₂ ratio measured by FTIR and EPMA, respectively, on H₂O-saturated experiments (green triangles). (b) NanoSIMS C⁻/Si⁻ ratio vs. CO₂/SiO₂ on CO₂-saturated experimental glasses (blue diamonds).

Thermo Scientific™ FLASH™ 2000 CHNS/O located at ISTO (see Table 2), measuring H concentration in glasses and hence, H₂O as follows. 10–15 mg of glassy material was first weighed, loaded to a tin capsule, and introduced into the combustion reactor via the Thermo Scientific MAS 200R Autosampler. The glass is then dropped into an oxidation/reduction reactor kept at a temperature of 900–1000 °C for its full combustion. The produced gases are carried out by a helium flow towards a layer filled with copper, then swept through a chromatographic column to sepa-

rate them, and finally, detected by a thermal conductivity detector (TCD).

Typically, each analysis started with a calibration step consisting of a series of blank measurements followed by standard inner measurements containing already known H₂O contents (from 2.74 to 12 wt.%). Each experimental glass set was then loaded and analysed to retrieve the hydrogen concentration which, via the previous calibration data, was finally used to calculate H₂O concentrations in glasses.

Absorbances of the fundamental OH-stretching vibration ($\sim 3520\text{ cm}^{-1}$) and the carbonate doublet ($\sim 1430\text{ cm}^{-1}$ and $\sim 1520\text{ cm}^{-1}$) in the mid-infrared (MIR) region, and the combination bands of molecular water (5200 cm^{-1}) and hydroxyl groups (4500 cm^{-1}) in the near-infrared region (NIR). Errors represent the standard deviations of the measured absorbances.

Thickness uncertainty correspond to the microscope instrumental error (0.0002 cm)

Density measured using Archimedes' method. Standard deviations correspond to 10-12 density measurements of each glass fragment
