Abstract

It is now clear that, in some parts of the ocean, inputs of hydrothermal iron (Fe) can make a more significant contribution to the Fe inventory than previously thought. While the Fe isotopic signature of seawater has proved useful for distinguishing between inputs of Fe from atmospheric deposition and seafloor sediments, the Fe isotope signature of hydrothermal vent fluids may change during mixing of vent fluids and seawater. To better constrain the processes leading to these changes, the Fe isotopic compositions ($\delta^{56}\text{Fe}$) of dissolved and total dissolvable Fe have been determined in high temperature vent fluids and the buoyant hydrothermal plumes at the Beebe and the Von Damm vent fields, which are located along the ultraslow Mid-Cayman spreading centre in the Caribbean Sea.

Our results show that the $\delta^{56}\text{Fe}$ value of dissolved Fe in the earliest stages of buoyant plume formation was lower (as low as -4.08‰) than measured in a high temperature, low-Mg, vent fluid sample (-0.28‰). This indicates that the iron isotopic signature of dissolved Fe is principally controlled by oxidation of Fe(II) and precipitation of Fe-(oxyhydr)oxides that

preferentially incorporate heavy Fe isotopes. In support of this, the $\delta^{56}\text{Fe}$ value of labile particulate Fe was higher than the $\delta^{56}\text{Fe}$ value of dissolved Fe. Nevertheless, at Beebe, the $\delta^{56}\text{Fe}$ value of total dissolvable Fe increased as the proportion of Fe predicted to have been lost from the plume increased, consistent with preferential fall-out of Fe-sulfides that are enriched in light Fe isotopes. The very low $\delta^{56}\text{Fe}$ values of dissolved Fe in the Beebe buoyant plume are consistent with (i) the high Fe/H₂S ratio of the vent fluids, and (ii) high Fe(II) oxidation rates, relative to other vent sites.

Key words

Iron isotopes, Hydrothermal plumes, Vent fluids, Beebe, Von Damm

1 Introduction

Iron (Fe) plays a key role in the oceanic carbon cycle because it regulates primary productivity in some parts of the world's ocean (*Boyd et al., 2007*). In those parts of the ocean where Fe is limiting, levels of the major nutrients (nitrate, phosphate and silicate) are high, which means that the operation of the carbon pump is highly inefficient and sequestration of atmospheric CO₂ is restricted (*Watson et al., 2000*). Determining and quantifying the main sources of Fe to the ocean is therefore critical. However, the relative contributions of different sources of Fe to the oceans remain uncertain as flux estimates from atmospheric dust, oceanic sediments and hydrothermal venting vary by orders of magnitude (*Tagliabue et al., 2010*).

Instrumental and methodological developments over the last two decades mean that it is now possible to accurately determine the stable isotope ratios of dissolved Fe in seawater, which facilitates 'fingerprinting' of Fe from different sources. The $\delta^{56}\text{Fe}$ signature of atmospheric aerosols is $\sim 0\text{‰}$, although the $\delta^{56}\text{Fe}$ value of Fe that dissolves from dust may be higher ($\sim +0.68\text{‰}$, *Conway and John, 2014*). Sedimentary Fe produced by dissimilatory Fe reduction carries a negative $\delta^{56}\text{Fe}$ signature (-3.3 to -1.8‰ , *Homoky et al., 2009; Severmann et al., 2006*), whereas sedimentary Fe produced by non-reductive dissolution processes has a heavier $\delta^{56}\text{Fe}$ value, $+0.07 \pm 0.07\text{‰}$ (*Homoky et al., 2021*). The $\delta^{56}\text{Fe}$ values of hydrothermal vent fluids are also distinct, ~ -0.67 to -0.12‰ (*Sharma et al., 2001; Beard et al., 2003; Severmann et al., 2004; Rouxel et al., 2008; Bennett et al., 2009; Klar et al., 2017; Syverson et al., 2017; Nasemann et al., 2018*), suggesting that Fe isotope signatures could be used to provide new information that would help constrain the oceanic cycle of Fe.

It was previously assumed that hydrothermal activity is not a major source of Fe because of precipitation of Fe-sulfides and Fe-(oxyhydr)oxides as Fe-rich high temperature hydrothermal vent fluids mix with seawater (*German et al., 1991*). However, studies have shown that a substantial portion of hydrothermal Fe may remain in the dissolved ($< 0.2 \mu\text{m}$) phase (e.g.,

Kleint *et al.*, 2016), and this Fe may be transported for thousands of kilometres away from the mid-ocean ridge (Saito *et al.*, 2013; Fitzsimmons *et al.*, 2014; Resing *et al.*, 2015). In support of this, numerical modelling studies have shown improved ability to reproduce Fe distributions when hydrothermal Fe sources were included (Tagliabue *et al.*, 2010). However, these models did not consider the distinctive behaviour of Fe within the proximal vs distal hydrothermal plume, or variations in Fe fluxes from different vent sites. Extending the models to incorporate these parameters, as well as increasing observations of Fe concentrations and Fe isotope distributions, particularly for hydrothermal systems, is critical for providing reliable predictions of future changes in the distribution of Fe and other micronutrients as well as carbon export.

Hydrothermal plumes are created as vent fluids mix with seawater, whereby steep gradients in temperature, pH and Eh lead to precipitation of metals as sulfides and oxides (Rudnicki and Elderfield, 1993). Fe isotope fractionation associated with these Fe precipitation pathways has been examined by analysis of particles within hydrothermal plumes at the Mid-Atlantic Ridge (Severmann *et al.*, 2004; Bennett *et al.*, 2009) and the East Pacific Rise (Rouxel *et al.*, 2016). More recent process studies at the East Scotia Ridge and the Vanuatu back-arc (Klar *et al.*, 2017; Lough *et al.*, 2017; Nasemann *et al.*, 2018) have shown that significant changes in $\delta^{56}\text{Fe}$ values of dissolved Fe occurred during plume rise and dispersal due to precipitation of Fe-sulfides and Fe-(oxyhydr)oxides that are, respectively, isotopically lighter and heavier, than the residual dissolved Fe. Iron that remains in the dissolved fraction may be stabilised in the form of nanoparticles and/or organic complexes (Toner *et al.*, 2009; Fitzsimmons *et al.*, 2017; Findlay *et al.*, 2019), contributing not only to the dissolved Fe budget but also the $\delta^{56}\text{Fe}$ signature of dissolved Fe in the wider deep ocean.

The aim of this study was to determine the behaviour of iron isotopes in two hydrothermal systems, the Beebe vent field (BVF) and the Von Damm vent field (VDVF), located along the

ultraslow Mid-Cayman spreading ridge (full spreading rate $<20 \text{ mm yr}^{-1}$) that bisects the Cayman Trough in the Caribbean Sea (Fig.1). This fills an important gap in knowledge, because ultraslow-spreading centres are under-sampled globally, and models of hydrothermal Fe inputs based on ridge spreading rates have typically assumed that vents located along ultraslow-spreading ridges represent an insignificant source of Fe (Tagliabue *et al.*, 2010; Resing *et al.*, 2015).

2 Sampling sites

The Beebe vent field is located at $18^{\circ}32.785'N$ $81^{\circ}43.080'W$ and in a water depth of 4960 m depth on the axis of the Mid-Cayman spreading ridge. It is the deepest hydrothermal vent field discovered to date, and the vent fluids are unusually buoyant such that the buoyant part of the hydrothermal plume extends up to 1200m above the seabed (Connelly *et al.*, 2012). Hydrothermal fluids circulate through mafic and ultramafic lithologies and the vent field consists of at least six discrete sulfide mounds, three of which host active sites of fluid venting (Beebe Woods, Beebe 125 and Deepest Vents). The Beebe vent field is also referred to as the 'Piccard' vent field in the literature; here we use the name 'Beebe' as this is the name listed in the InterRidge database after venting was visually confirmed at the seafloor (Connelly *et al.*, 2012).

The Von Damm vent field is located at $18^{\circ}22.605'N$ $81^{\circ}47.875'W$ at 2300 m water depth, on the upper slopes of an oceanic core complex, 13 km west of the spreading axis and ~20 km away from Beebe (Fig.1). Tectonic exposure of lower crustal and upper mantle rocks gives rise to a heterogeneous basement (Hodgkinson *et al.*, 2015). Particle-poor hydrothermal fluids have been observed emanating from a series of talc chimneys, called Main Spire, Hotter than Hole, X15 and Chimlets (Hodgkinson *et al.*, 2015).

The local surrounding deep seawater mass at both sites has a temperature of 3.98°C, a salinity of 34.988, and an O₂ concentration of ~220 µM (Connelly *et al.*, 2012), similar to North Atlantic Deep Water (NADW).

3 Methods

3.1 Sample collection

Hydrothermal vent fluids, and fluids from the buoyant hydrothermal plume, were sampled during RRS *James Cook* cruise JC82 in February 2013. Gas tight fluid samplers were employed to collect vent fluid samples from different chimneys, and temperatures were measured separately within the orifice using a probe deployed by the remotely operated vehicle (ROV) *Isis*. The vent fluid samples were then transferred into acid-cleaned polyethylene (PE) vials and were acidified on board to 0.015 M with ultra-pure nitric acid (*Romil*), for analysis back in the laboratory. Any precipitates that formed in the gas-tight samplers were re-dissolved and accounted for in the final element concentrations.

Hydrothermal plumes were detected using a Seabird 911 plus conductivity, temperature and depth (CTD) profiler system together with a light scattering sensor (LSS) and an Eh electrode. The buoyant part of the hydrothermal plumes was identified by positive LSS and temperature anomalies and a negative Eh anomaly. At Beebe, the buoyant hydrothermal plume rises a considerable distance (up to 1200 m) above the seabed (Connelly *et al.*, 2012); we distinguish between plume samples that have Mn concentrations of >20 nM (which represent the earliest stages of buoyant plume formation) from plume samples that have Mn concentrations of <20 nM (which represent the latter stages of buoyant plume formation). The cut-off Mn = 20 nM corresponds to a vent fluid dilution factor of ~30,000 at Beebe and ~900 at Von Damm (see [Section 4.2](#)).

Water samples from the buoyant plume at Beebe (3-241 m above the seabed) were collected using 10 L Ocean Test Equipment (OTE) water sampling bottles mounted on a titanium rosette deployed from the ship. At Von Damm, plume samples were collected 1-23 m above the seabed using 1.2 L OTE bottles attached to the ROV *Isis*. Both sets of OTE bottles were modified for trace metal sampling and were pre-cleaned. Upon retrieval of the OTE bottles, ~500 mL of unfiltered seawater was collected for analysis of total dissolvable (TD) iron and manganese (Mn). The rest of the seawater sample was then filtered as soon as possible (within ~4 h of the sample bottle closing) through a polycarbonate membrane filter (0.2 μ m, Whatman) under gentle pressure, for collection of dissolved Fe (dFe) and Mn (dMn). Note that although the relatively low pH of buoyant plume waters means that the half-life for Fe(II) oxidation will be substantially longer than it is in bottom seawater (0.28 h at Beebe and 0.45 h at Von Damm; *Lough et al., 2019a, b*), changes in Fe speciation may have occurred between closure of the sampling bottle and filtration. Both sets of samples were stored in acid-cleaned low density polyethylene bottles (LDPE), and were acidified to pH ~1.8 with ultra-pure nitric acid (*Romil*). Thus, dFe is defined as Fe that is retained in seawater filtered at <0.2 μ m, whereas TDFe consists of both dFe and Fe from the labile fraction of suspended particles (that is, Fe leached by addition of 0.03 M HNO₃ during storage for >6 months). All sample bottles were bagged and shipped back to the laboratory for further analysis.

3.2 Fe isotope analysis

The iron isotope compositions of hydrothermal vent fluids and plume samples were determined using a double spike technique, adapted from *Lacan et al. (2010)*. All acids used for chemical processing were thermally distilled. Milli-Q (MQ, 18.2 M Ω) water was used for diluting and cleaning. LDPE bottles and Perfluoroalkoxy (PFA) vials were thoroughly cleaned for trace

metal purposes. Samples were handled under laminar flow hoods, set within Class 100 clean laboratories at the University of Southampton.

Hydrothermal plume samples (dissolved and total dissolvable phases) were pre-concentrated using NTA Superflow (Qiagen) resin. Columns were made with PFA tubing and a polyethylene (PE) frit, and loaded with ~1 mL of clean NTA resin. The sample pH was adjusted to between 1.7-1.8 and 10 μ M UpA-grade hydrogen peroxide (H_2O_2 , Sigma Aldrich) was added to the sample ~30 min prior to starting the pre-concentration procedure. Between uses and before loading a sample, the resin was cleaned with 75 mL 1.5 M HCl and 80 mL MQ. The sample was passed over the resin by gravity flow, and the resin was then rinsed with MQ water to remove residual salts. The Fe fraction was eluted with 10 mL of 1.5 M HCl, collected in an acid cleaned PFA vial (Savillex), and subsequently evaporated on a hotplate at ~90°C and reconstituted in 5M HCl (with 0.001% H_2O_2) for further analysis.

Iron can be efficiently separated from cations such as Cr and Ni that also bind to NTA resin, by conversion to FeCl_4^- in strong HCl and purification by anion exchange. Approximately 200 μ L of cleaned AG-MP1 resin (BioRad) was loaded in handmade micro columns (PE material, ~8 cm length and ~3 mm diameter). Each column was pre-cleaned by addition of 1 mL of 2 M HNO_3 and conditioned by addition of 0.2 mL of 5 M HCl (with 0.001% H_2O_2), before loading the sample in 5 M HCl (with 0.001% H_2O_2). Matrix elements were eluted with 1 mL of 5 M HCl (with 0.001% H_2O_2). Then the Fe fraction was eluted with 1 mL of 1 M HCl into a clean Savillex vial, and was dried down gently and re-dissolved in 0.3 M HNO_3 .

No pre-concentration was needed for the vent fluids, as they exhibit much higher Fe concentrations than plume samples. Prior to purification on the anion exchange column, the vent fluid samples were oxidised by reflux with concentrated HNO_3 and H_2O_2 .

The Fe isotopic composition was determined by multicollector inductively coupled plasma mass spectrometry (MC-ICP-MS; Thermo Fisher Neptune Plus). Instrumental mass bias was corrected using a ^{57}Fe - ^{58}Fe double spike, which was added in equi-molar concentration to the sample before chemical processing. The isotope values are reported in delta notation relative to the Fe isotope reference material IRMM-14 and expressed as:

$$\delta^{56}\text{Fe} (\text{‰}) = [({}^{56}\text{Fe}/{}^{54}\text{Fe})_{\text{sample}}/({}^{56}\text{Fe}/{}^{54}\text{Fe})_{\text{IRMM-14}} - 1] \times 1000 \quad (1)$$

Samples with $\sim 100 \text{ ng mL}^{-1}$ Fe were introduced to the plasma using an Apex-Q desolvator (ESI) and signals from ^{54}Fe , ^{56}Fe , ^{57}Fe , ^{58}Fe , ^{53}Cr , ^{60}Ni were quantified. Analysis by MC-ICP-MS was carried out in high-resolution mode, and each sample measurement consisted of 50 individual measurement cycles. The instrument was carefully tuned to give sufficient mass resolution (>8000), before running a sequence that consisted of analysis of the reference material (IRMM), the internal Fe standard (ETH), Sample 1, Sample 2, then back to the IRMM reference material again. The wash time was 70 s before analysis of each sample/standard and 420 s before the analysis of blanks. The mean beam intensity of a blank solution that was analysed before and after each sample/standard was subtracted. Mass bias was corrected by iteratively deconvolving the spike-sample mix based on data reduction methodology (*Albarède and Beard, 2004*). Long-term analysis of the ETH iron isotope standard gave $\delta^{56}\text{Fe} = +0.51 \pm 0.09\text{‰}$ (2SD, $n=45$), in agreement with the consensus value ($+0.52 \pm 0.08\text{‰}$; *Lacan et al., 2010*). We apply $\pm 0.09\text{‰}$ as an estimate of reproducibility of the $\delta^{56}\text{Fe}$ values for all samples in this study.

The overall procedural (preconcentration and purification) Fe blank was $1.54 \pm 0.74 \text{ ng}$ ($n=2$). The accuracy of the method was validated through the analysis of trace metal free seawater doped with the hematite (HEM) iron isotope standard, yielding an average $\delta^{56}\text{Fe}$ value of $+0.22 \pm 0.10\text{‰}$ (2SD, $n=5$), consistent with previously published HEM values ($\delta^{56}\text{Fe} = +0.24 \pm 0.05\text{‰}$; *Klar et al., 2017*).

3.3 Ancillary analyses

The vent fluids were diluted 100-2500 fold with 0.3 M HNO₃ and concentrations of major and minor cations were determined by inductively coupled plasma atomic adsorption spectroscopy (ICP-AES; iCAP 6000, Thermo Scientific) and ICP-MS (X-series, Thermo Scientific). Chloride (Cl) concentrations were measured by ion chromatography (Dionex), and hydrogen sulfide was measured immediately after recovery of the gas tight fluid sampler by iodometric titration.

The Fe and Mn concentrations in the hydrothermal plume samples were measured by ICP-MS (Element XR, Thermo Scientific) after pre-concentration on a chelating resin using an offline extraction system as discussed in *Lough et al. (2019a)* and *Lough et al. (2019b)*. The initial determinations of dissolved and total dissolvable Fe (dFe and TDFe) concentrations were used to estimate the sample volume required for ~100 ng of Fe for the isotopic analysis.

The reported Fe concentration data are from the MC-ICP-MS measurements. Iron concentrations were determined simultaneously with the isotope ratio measurements via isotope dilution equations, based on the known sample volume and the quantity of added spike. The uncertainty of these measurements was less than $\pm 1\%$. The MC-ICP-MS data were within 20% (with two exceptions) of the concentration measured by ICP-MS.

4 Results

4.1 Hydrothermal vent fluids

The chemical compositions of vent fluid samples analysed for $\delta^{56}\text{Fe}$ are shown in [Table 1](#), and the compositions of all vent fluid samples collected on cruise JC82 are given in the [Supplementary Information \(Table S1\)](#). At Beebe, the vent fluids had relatively high

temperatures (350 to 401 °C) and low pH (2.9 to 3.1) compared to vent fluids from Von Damm (temperatures up to 215 °C and pH = ~6-7).

The sampled vent fluid compositions can be assumed to reflect two-component mixing of a hydrothermal ‘end-member’ fluid that contains no magnesium (Mg) with bottom seawater (*Bischoff and Dickson, 1975*). Based on this assumption, the samples analysed for $\delta^{56}\text{Fe}$ from Beebe consisted of >90% hydrothermal fluid, whereas the sample from Von Damm with lowest Mg consisted of ~70% hydrothermal fluid. Vent fluid samples with low Mg (as low as 2.5 mM) have nevertheless been collected from Von Damm during other sampling campaigns (*McDermott, 2015*).

Based on the extended vent fluid data ([Table S1](#)), and by extrapolation to zero-Mg, the hydrothermal end-member Mn and Fe concentrations at the Beebe vent field were, respectively, 597 ± 10.4 (Beebe 125) to 618 ± 6.0 μM (Deepest Vents) and 6320 ± 209 (Beebe 125) to 8150 ± 1990 μM (Deepest Vents), similar to end-member fluid compositions (567-571 μM Mn and 6660-12800 μM Fe) reported by *McDermott et al. (2018)* for the same study area. The estimated end-member H_2S concentrations (3.8 ± 0.34 mM (Beebe 125) to 6.8 ± 1.0 mM (Deepest Vents)) were lower than measured previously (~12 mM; *McDermott et al., 2018*). Estimated end-member Cl concentrations (366 ± 5.8 mM for Beebe 125 and 364 ± 2.6 mM for Deepest Vents) were lower than background seawater (~550 mM), which has been attributed to phase separation (*McDermott et al., 2018*).

Using the same methodology, the end-member vent fluids from Main Spire at the Von Damm vent field had Mn = 11.6 ± 0.44 μM and Fe = 22.5 ± 4.2 μM , within the range (8.9-11.3 μM for Mn and 21-46 μM for Fe) of low Mg (2.5-14.8 mM) fluids reported by *McDermott (2015)*. As no samples with low Mg concentrations were collected at Hotter than Hole and Chimlet 2, we could only estimate minimum values for the end-member contents for non-conservative elements; for Mn the minimum value was 22.5 ± 4.2 μM and for Fe the minimum value was

412±137 µM. The minimum end-member H₂S concentrations were ~1.6±0.3 mM for Main Spire and ~1.2±0.5 mM for Hotter than Hole and Chimlet 2, slightly lower than values reported for low Mg vent fluids from East Summit (3.3 mM; *McDermott, 2015*). The estimated end-member chloride contents of the Von Damm vent fluids (686±26 mM for Main Spire, 681±12 mM for Hotter than Hole and Chimlet 2) were slightly higher than background seawater (~546 mM), which has been attributed to hydration reactions during serpentinization that remove water from the circulating fluids (*Hodgkinson et al., 2015*).

At the Beebe vent field, the sample with lowest Mg had a δ⁵⁶Fe value of -0.28‰, within the range of high-temperature fluids from basalt-hosted hydrothermal fields on the Mid-Atlantic Ridge (-0.5 to -0.2‰; *Bennett et al., 2009; Severmann et al. 2004*). At the Von Damm vent field, the δ⁵⁶Fe value of the fluid sample with lowest Mg was slightly higher, +0.08‰.

4.2 Dissolved and total dissolvable Fe concentrations in the buoyant hydrothermal plumes

The dFe and TDFe concentrations in buoyant plume samples from the Beebe and Von Damm vent fields are plotted against the vent fluid dilution factor in [Fig. 2a](#). The vent fluid (VF) dilution factor is given by $([Mn]_{VF} - [Mn]_{SW}) / ([Mn]_{sample} - [Mn]_{SW})$, where [Mn] represents Mn concentration and SW represents background seawater. [Mn]_{VF} was 597-618 µM for Beebe and 11.6-22.5 µM for Von Damm ([Table 1](#)), and [Mn]_{SW} was 0.1 nM (*Lough et al., 2019a*). The VF dilution factor varied between ~3,000 and 70,000 at Beebe, whereas between ~60 and 10,000 at Von Damm. As Mn shows near-conservative behaviour during mixing of vent fluids and seawater over timescales of weeks, it therefore serves as a tracer of hydrothermal plume dispersal on the spatial scale that we sampled.

At both vent fields, concentrations of TDFe and dFe were lower at higher VF dilution factor ([Fig. 2a](#)), as the hydrothermal fluids mix with background seawater with low Fe. At Beebe,

concentrations of TDFe were $\sim 30\text{--}73\%$ (average $53 \pm 15\%$) lower than predicted for conservative mixing between the vent fluid and seawater, indicating that Fe was removed from the TD fraction, most likely by fall-out of sulfide particles as soon as the vent fluids were expelled at the seabed (*Rudnicki and Elderfield, 1993; Lough et al., 2019a*). However, at Von Damm, concentrations of TDFe in the plume were generally within the range predicted by conservative mixing, suggesting that particle fall-out at this site was minimal (*Lough et al., 2019b*).

Concentrations of dFe at Beebe and Von Damm, respectively, ranged from 16.1 to 86.5 nM and 21.0 to 62.6 nM. These values are significantly higher than background seawater (0.77 nM in the Cayman Trench; *Lough et al., 2019a*). In general, the ratio of dFe/TDFe increased as the plume became more dilute, varying from $< \sim 10\%$ in the earliest stages of buoyant plume formation to up to $\sim 60\%$ at higher VF dilution factors. Thus, a higher proportion of Fe is present in the labile particulate fraction close to the vent source.

4.3 Isotopic composition of dFe and TDFe in the buoyant hydrothermal plumes

The $\delta^{56}\text{Fe}$ values of dFe showed notable changes as the buoyant plume became more dilute ([Fig. 2b](#); [Table S2](#)). At the Beebe vent field, samples from the least dilute part of the plume had very low $\delta^{56}\text{Fe}$ values (as low as -4.08‰), indicating enrichment of light Fe isotopes relative to the end-member vent fluid. At the Von Damm vent field, $\delta^{56}\text{Fe}$ values of dFe were as low as -2.49‰ . These dFe isotope compositions are lighter than those reported for plume samples recovered from the Mid-Atlantic Ridge, East Scotia Ridge, East Pacific Rise, and the Vanuatu back-arc basin (-2.39 to -0.13‰ ; *Conway and John et al., 2014; Klar et al., 2017; Lough et al., 2017; Fitzsimmons et al., 2017; Nasemann et al., 2018*). As the plumes became more dilute,

the $\delta^{56}\text{Fe}$ values of dFe increased; samples with the lowest dMn concentrations (9 nM and 2 nM) had $\delta^{56}\text{Fe}$ values of +0.29‰ and +0.22‰ at Beebe and Von Damm, respectively.

The $\delta^{56}\text{Fe}$ value of TDFe showed less variation during plume mixing, ranging from -0.22 to +0.42‰ at both sites (Fig. 2b; Table S2). The average $\delta^{56}\text{Fe}$ value of TDFe in the Beebe plume (+0.11‰) was higher than that in the Von Damm plume (-0.07‰), and higher than the $\delta^{56}\text{Fe}$ value of the low-Mg Beebe vent fluid (-0.28‰). At Von Damm, the $\delta^{56}\text{Fe}$ value of the vent fluid with lowest Mg (+0.08‰) was within the range of $\delta^{56}\text{Fe}$ values of TDFe (-0.22 to +0.13‰) measured in the plume.

The concentration of labile particulate Fe (LPFe) was determined from the difference in the concentrations of TDFe and dFe. The Fe isotopic composition of LPFe can then be estimated by mass balance. $\delta^{56}\text{Fe}$ values of LPFe ranged from +0.09 to +0.71‰ in the Beebe plume and were highest during the early stages of buoyant plume formation (VF dilution factor < 30,000). At Von Damm, $\delta^{56}\text{Fe}$ values of LPFe ranged from -0.38 to +0.48‰ but there was no obvious shift in LPFe $\delta^{56}\text{Fe}$ values as the plume became more dilute.

4.4 Incubation experiment

To investigate how concentrations of dFe and $\delta^{56}\text{Fe}$ values of dFe may evolve over time, an on-board incubation experiment was carried out. One 10 L water sample (sample JC82-CTD11-N4) from the buoyant plume from the Beebe vent field was stored at 5°C in its OTE sampling bottle for between 6 to 16 h after the sample bottle was closed before it was filtered. Over this time period, the concentration of dMn stayed the same (22 ± 0.5 nmol/kg; *Lough et al., 2019a*), but the concentration of dFe decreased from 28.9 nM to 7.4 nM (Table S3). Over the same time interval, the $\delta^{56}\text{Fe}$ value of dFe increased from -0.37‰ to +0.51‰. These data

indicate that, for this buoyant plume sample, isotopically light Fe was being removed from the dissolved fraction over time.

5 Discussion

5.1 Fe isotope composition of the hydrothermal vent fluids

The $\delta^{56}\text{Fe}$ values of the low-Mg Beebe vent fluids ranged from -0.28 to -0.10‰ , within the range of low-Mg hydrothermal fluids from ultramafic- and basalt-hosted hydrothermal systems measured from around the world to date (-0.67 to -0.12‰ ; [Table S4](#)). These values are systematically lower than unaltered mid-ocean ridge basalt ($\delta^{56}\text{Fe} = +0.1 \pm 0.01\text{‰}$; *Teng et al., 2013*), which has been attributed to preferential leaching of light Fe isotopes during alteration (*Rouxel et al., 2008*). Other processes, such as secondary mineral formation in the reaction zone and Fe-sulfide precipitation in the shallow seafloor, may also cause fractionation of Fe isotopes (*Rouxel et al., 2003; Rouxel et al., 2004*), but phase separation and variations in host rock lithology appear to be a minor control on the Fe isotope composition of vent fluids (*Beard et al., 2003; Bennett et al., 2009; Syverson et al., 2014*).

At the Von Damm vent field, the $\delta^{56}\text{Fe}$ values of vent fluids range from -0.90 to $+0.08\text{‰}$, and the values decrease with increasing Mg. The sample with the lowest Mg (14.5 mM) is isotopically heavy ($\delta^{56}\text{Fe} = +0.08\text{‰}$) relative to fluids from other hydrothermal sites that have a low Mg content ([Table S4](#)). The hydrothermal fluids likely underwent mixing with seawater circulating in the shallow subsurface prior to venting (*McDermott, 2015; Hodgkinson et al., 2015*). In these circumstances, a fraction of Fe from the hydrothermal fluid may precipitate as Fe-sulfides that are preferentially enriched in light Fe isotopes (*Butler et al., 2005; Syverson et al., 2013*), leaving the residual Fe isotopically heavier. The combined effects of subsurface conductive cooling of hydrothermal fluids and mixing with seawater, leading to precipitation

of sulfides with low $\delta^{56}\text{Fe}$ values of -2 to -1% , have previously been documented at the Lucky Strike vent field on the Mid-Atlantic Ridge (*Rouxel et al., 2004*).

5.2 Impact of iron precipitation on Fe isotopes as Beebe vent fluids are expelled at the seafloor

As discussed in [Section 4.2](#), when the hot Fe- and H_2S -rich Beebe vent fluids come into contact with cold seawater, some part of the Fe appears to immediately precipitate, most likely as Fe-sulfide (FeS and FeS_2 ; *Rudnicki and Elderfield, 1993*). Precipitation of Fe-sulfide would leave the residual dFe enriched in the heavier Fe isotopes (*Butler et al., 2005*) and, based on analyses of buoyant plume particles, the estimated difference between the $\delta^{56}\text{Fe}$ value of the Fe-sulfide particles and dissolved Fe ($\delta^{56}\text{Fe}_{\text{FeS}} - \delta^{56}\text{Fe}_{\text{dFe}}$) is -0.60% (*Bennett et al., 2009*). The $\delta^{56}\text{Fe}$ value of the Fe remaining in the dissolved phase after sulfide precipitation (Equation 2), and the accumulated Fe-sulfide precipitates (Equation 3), can be estimated using a Rayleigh fractionation model:

$$\delta^{56}\text{Fe}_{\text{dFe}} = (\delta^{56}\text{Fe}_{\text{VF}} + 1000) \cdot f^{\alpha-1} - 1000 \quad (2)$$

$$\delta^{56}\text{Fe}_{\text{FeS}} = (\delta^{56}\text{Fe}_{\text{VF}} + 1000) \cdot \frac{1-f^{\alpha}}{1-f} - 1000 \quad (3)$$

where $\delta^{56}\text{Fe}_{\text{VF}}$ is the Fe isotope composition of the end-member vent fluid, α is the fractionation factor between FeS and dFe (~ 0.9994 ; assuming $\alpha \approx e^{\delta^{56}\text{Fe}_{\text{FeS}} - \delta^{56}\text{dFe}}$), and f is the proportion of Fe that remains in the dissolved phase, based on the ratios of measured to calculated TDFe concentrations ([Table S2](#)).

While sulfide particles have not been observed in the buoyant plume at Von Damm (*Lough et al., 2019b*), at Beebe, f has an average value of ~ 0.47 , meaning that close to 50% of the vent fluid Fe precipitated as soon as the vent fluids emerged at the seabed ([Section 4.2](#)). If all of the dFe lost as the vent fluids emerged at the seabed was precipitated as FeS, and given that $\delta^{56}\text{Fe}_{\text{VF}}$

= -0.28‰, then the $\delta^{56}\text{Fe}$ value of the residual dissolved Fe would be $\sim +0.17\text{‰}$, far higher than the values measured in the samples collected during the early stages of plume formation (-4.08 to -1.43‰).

5.3 Fractionation of Fe isotopes in the buoyant plume due to Fe(II)-Fe(III) oxidation

The $\delta^{56}\text{Fe}$ values of dFe in the buoyant plume samples are lower than that of Fe in the hydrothermal fluid and evolve towards higher $\delta^{56}\text{Fe}$ with increasing plume dilution (Fig. 2b). This strongly suggests that the iron isotopic signature of dFe in the buoyant plume samples was principally controlled by oxidation of Fe(II) to Fe(III) as the vent fluids mix with oxygenated seawater. Experimental and theoretical studies have shown that oxidation of $\text{Fe(II)}_{\text{aq}}$ enriches heavy Fe isotopes in $\text{Fe(III)}_{\text{aq}}$, and the difference between $\delta^{56}\text{Fe(III)}_{\text{aq}}$ and $\delta^{56}\text{Fe(II)}_{\text{aq}}$ can be up to 3.56‰ (Welch *et al.*, 2003; Anbar *et al.*, 2005). $\text{Fe(III)}_{\text{aq}}$ is not stable in seawater and forms (i) colloidal (operationally defined as between 0.02 and 0.2 μm diameter) Fe-(oxyhydr)oxides (FeOOH), which subsequently aggregate and coagulate into larger particles ($>0.2 \mu\text{m}$), and/or (ii) organically-bound Fe(III). The proportion of organically-bound Fe(III) relative to FeOOH has however been shown to be negligible in hydrothermal plumes within $\sim 100 \text{ km}$ of a vent field (Fitzsimmons *et al.*, 2017). Under equilibrium conditions, the fractionation between $\text{Fe(II)}_{\text{aq}}$ and FeOOH is very similar to that between $\text{Fe(II)}_{\text{aq}}$ and $\text{Fe(III)}_{\text{aq}}$, meaning that there is no or very limited isotope fractionation between $\text{Fe(III)}_{\text{aq}}$ and FeOOH (Wu *et al.*, 2011). Therefore, the overall effect of oxidation of Fe(II) to Fe(III) and the formation of Fe-(oxyhydr)oxides is the preferential removal of the heavier Fe isotopes from the dissolved Fe pool.

Assuming the variation in the Fe isotope composition of dFe is controlled by Fe(oxyhydr)oxide formation, then the $\delta^{56}\text{Fe}$ value of dFe in the buoyant plume is a function of the proportion (F)

of dFe remaining as Fe(II) and the proportion (X) of Fe(III) remaining in the dissolved (colloidal) fraction. This can be modelled as a Rayleigh fractionation process as follows (*Klar et al., 2017; Lough et al., 2017; Nasemann et al., 2018*):

$$\delta^{56}\text{Fe(II)} = (\delta^{56}\text{Fe(II)}_0 + 1000) \cdot F^{\alpha-1} - 1000 \quad (4)$$

$$\delta^{56}\text{Fe(III)} = (\delta^{56}\text{Fe(II)}_0 + 1000) \cdot \frac{1-F^{\alpha}}{1-F} - 1000 \quad (5)$$

where $\delta^{56}\text{Fe(II)}$ is the isotopic composition of the remaining Fe(II), $\delta^{56}\text{Fe(II)}_0$ is the initial isotopic composition of dissolved Fe(II) before oxidation starts, $\delta^{56}\text{Fe(III)}$ is the iron isotopic composition of the accumulated Fe(III) precipitate, and α is the fractionation factor between aqueous Fe(II) and precipitated Fe(III) ($\alpha_{\text{Fe(III)-Fe(II)}} \sim 1.0035$ at a temperature of 4°C; *Welch et al., 2003*). The initial isotopic composition of dissolved Fe(II) before oxidation starts is the $\delta^{56}\text{Fe}$ value of Fe in the vent fluid at Von Damm (i.e. $\delta^{56}\text{Fe(II)}_0 = +0.08\text{‰}$) but, at Beebe, because ~50% of the vent fluid Fe immediately precipitates as the vent fluids are expelled at the seabed, $\delta^{56}\text{Fe(II)}_0 \approx +0.17\text{‰}$ ([Section 5.2](#)). Assuming that FeOOH precipitates at a constant rate, the $\delta^{56}\text{Fe}$ value of dFe delivered to the plume is given by (*Klar et al., 2017*):

$$\delta^{56}\text{Fe} = \frac{F \cdot \delta^{56}\text{Fe(II)} + X \cdot (1-F) \cdot \delta^{56}\text{Fe(III)}}{F + X \cdot (1-F)} \quad (6)$$

Based on the measured ratios of dFe/TDFe in the buoyant plume samples with [Mn] >20 mM, the proportion of Fe(III) that precipitated can be estimated, and was $\geq 83\%$ at Beebe and $\geq 78\%$ at Von Damm. As Fe(II) must reside exclusively in the dissolved fraction then the proportion of Fe(II) that is oxidised to Fe(III) must also be $\geq 78\%$. The results of this modelling exercise are shown in [Fig. 3a](#). The low $\delta^{56}\text{Fe}$ values (-4.08 to -0.60‰) in the least dilute buoyant plume samples are well described by the Rayleigh model: the lowest $\delta^{56}\text{Fe}$ value, -4.08‰ at Beebe, is consistent with oxidation of ~94% Fe(II) to Fe(III) followed by precipitation of ~89% Fe(III) as FeOOH, which is consistent with our measured concentrations of dFe and TDFe.

As the buoyant plumes become more dilute (lower Mn concentration), $\delta^{56}\text{Fe}$ values of dFe increase (to +0.22 to +0.29‰). This can be partly explained by near-quantitative oxidation of Fe(II), but it is also consistent with: (i) exchange of Fe between the particulate and dissolved fractions, whereby isotopically heavy Fe is re-released from Fe-(oxyhydr)oxides (*Fitzsimmons et al., 2017; Lough et al., 2019a, 2019b*); and/or (ii) an increase in the proportion of dFe that is complexed by organic ligands (*Fitzsimmons et al., 2017*) as organically bound Fe(III) is isotopically heavy relative to unbound Fe(III) by up to +0.6‰ (*Dideriksen et al., 2008; Morgan et al., 2010*).

5.4 Behaviours of Fe-sulfide and Fe-(oxyhydr)oxide particles in the buoyant plume

While precipitation of Fe-(oxyhydr)oxides (that preferentially incorporate heavy Fe isotopes) is the principal control on the iron isotopic composition of dFe delivered to the buoyant plume ([Section 5.3](#)), we note that the $\delta^{56}\text{Fe}$ value of TDFe increases as the proportion of Fe predicted to have been lost from the plume increases ([Fig. 3b](#)). This suggests that Fe loss from the buoyant plume primarily occurs via fall-out of Fe-sulfides that are relatively enriched in light Fe isotopes. Fe-sulfide particles are relatively dense compared to Fe-(oxyhydr)oxides and will settle out of the plume more quickly (*Lough et al., 2017*).

By contrast, Fe-(oxyhydr)oxides have relatively small particle size and tend to remain in the plume after they form (*Fitzsimmons et al., 2017; Lough et al., 2019a*). In support of this, calculated $\delta^{56}\text{Fe}$ values of the labile particulate fraction (LPFe) are higher (−0.13 to +0.71‰) in the earliest stages of buoyant plume formation than the $\delta^{56}\text{Fe}$ values of dFe. The calculated $\delta^{56}\text{Fe}$ values of LPFe are generally similar to or slightly lower than the $\delta^{56}\text{Fe}$ values of the accumulated Fe(III) precipitate predicted by Rayleigh modelling ([Fig. 3a](#)). The slightly lower than predicted LPFe $\delta^{56}\text{Fe}$ values, at least at Beebe, may be due to the presence of Fe-sulfides

in the labile particulate fraction, but we also note that weak acid leaching of natural particles may fractionate Fe isotopes to a small extent (e.g., *Dunlea et al., 2021*).

5.5 Evidence for coagulation of Fe-sulfide nanoparticles in the buoyant plume

Results of the incubation experiment show that the concentration of dFe in the buoyant plume sample progressively decreased over time whereas the $\delta^{56}\text{Fe}$ values of dFe increased (Fig. 4a), consistent with preferential loss of light Fe isotopes from the dissolved fraction. As the half-life for Fe(II) oxidation at Beebe is short (0.28 h; *Lough et al., 2019a*), Fe(II) oxidation was essentially complete by the time the first sub-sample was collected 6 hours after the sample bottle was closed (see Section 4.4). This means that changes in $\delta^{56}\text{Fe}$ values cannot be attributed to Fe(II) oxidation which, in any case, would remove Fe that is preferentially enriched in heavy Fe isotopes, decreasing (rather than increasing) the $\delta^{56}\text{Fe}$ value of Fe that remains in the dissolved fraction.

The $\delta^{56}\text{Fe}$ value of accumulated Fe-sulfides in the Beebe buoyant plume was estimated to be -0.68‰ (Equation 3, $f = \sim 0.47$). If removal of dFe in the incubation experiment occurred solely via progressive coagulation of Fe-sulfides that are presumably in the form of nanoparticles (constituting at least $\sim 75\%$ of the dFe fraction), and assuming there was no isotope fractionation between coagulated Fe-sulfide particles and the remaining dFe, then mass balance calculations (Table S3) indicate that the $\delta^{56}\text{Fe}$ value of dissolved Fe should increase as the proportion of Fe that remains in the dissolved fraction decreases, consistent with our observations (Fig. 4c). Whilst sulfide formation must have occurred before Fe oxidation starts (e.g. *Rudnicki and Elderfield, 1993*) and accounts for $\sim 50\%$ loss of hydrothermal Fe(II) as the vent fluids are expelled at the seabed, our incubation experiment indicates that nanoparticulate Fe-sulfides can be retained in the dissolved Fe pool as the plume evolves, coagulating and

settling out of the plume over time. In support of this, SEM-EDX images of particles from the Beebe plume have revealed the presence of large ($\sim 10\ \mu\text{m}$) FeS_2 particles likely derived from precipitation and coagulation of nanoparticulate FeS_2 ($<0.2\ \mu\text{m}$) that formed as the vent fluids emerged at the seabed (Lough *et al.*, 2019a). Formation of FeS_2 nanoparticles has also been directly observed in nascent plumes forming above high-temperature vents at the East Pacific Rise (Yücel *et al.*, 2011; Findlay *et al.*, 2019).

There is some evidence that scavenging of dFe also increases the $\delta^{56}\text{Fe}$ value of Fe that remains in the dissolved fraction, by up to $\sim 0.3\text{‰}$ (e.g., John and Adkins, 2012). Scavenging could explain the $\delta^{56}\text{Fe}$ value of the second sub-sample that was collected $\sim 8\ \text{h}$ after the sample bottle was closed (Fig. 4d), but the rest of the incubation experiment data are more consistent with loss of dFe due to coagulation of Fe-sulfide nanoparticles (Fig. 4c). Finally, we note that our incubation experiment data are not consistent with coagulation and precipitation of organically-bound Fe(III) colloids that are isotopically heavy relative to unbound Fe(III) (and Fe(II)) (Dideriksen *et al.*, 2008; Morgan *et al.*, 2010; Fitzsimmons *et al.*, 2017).

By contrast, a similar incubation experiment carried out on a buoyant plume sample collected from the E2 hydrothermal site on the East Scotia Ridge (Lough *et al.*, 2017) revealed that while dFe concentrations decreased over time between sampling and filtering, the $\delta^{56}\text{Fe}$ value of dFe decreased (Fig. 4b), consistent with oxidation of Fe(II) and precipitation of the Fe(III)-(oxyhydr)oxides that form. It is important to note, however, that the oxidation half-life of Fe(II) is significantly longer at E2 (1.45 to 5.63 h; Lough *et al.*, 2017) than it is at Beebe ($\sim 0.28\ \text{h}$), such that the number of oxidation half-lives between sampling and filtering of the sample from the E2 plume was significantly lower (1-2 half-lives) than the number of oxidation half-lives between sampling and filtering of the sample from the Beebe plume (>10 half-lives). This means that Fe(II) oxidation was continuing throughout the incubation at E2, but was essentially complete by the time the first sub-sample was taken at Beebe.

5.6 Controls on the $\delta^{56}\text{Fe}$ signature of dissolved Fe in hydrothermal plumes

The key roles of iron sulfide and iron (oxyhydr)oxide formation on the evolution of the iron isotopic composition of dFe as vent fluids mix with seawater on the Mid-Cayman ultra-slow spreading ridge is consistent with observations made at other vent sites (e.g., *Bennett et al., 2006; Rouxel et al., 2016; Fitzsimmons et al., 2017; Klar et al., 2017; Lough et al., 2017; Nasemann et al., 2018*). [Fig. 5](#) compares the range of measured $\delta^{56}\text{Fe}$ values of dFe in hydrothermal plumes published to date with the Fe/H₂S ratio of the end-member vent fluids and the Fe(II) oxidation rate in overlying seawater. If the sample from Pele's Pit that represents mixing between seawater and a low temperature fluid with high Mg is excluded, then there is a general trend towards lower $\delta^{56}\text{Fe}$ values for dFe in the hydrothermal plume at vent sites that have higher vent fluid Fe/H₂S (not significant at $P < 0.1$) and bottom waters that promote faster Fe(II) oxidation rates (i.e. bottom waters with relatively high dissolved oxygen and high pH; *Field and Sherrell, 2000*) (significant at $P < 0.1$). The very low $\delta^{56}\text{Fe}$ values of dFe at Beebe (as low as -4.08‰) reflect (i) the relatively high Fe/H₂S ratio (~ 1.2 - 1.7) of the vent fluids that means that a greater proportion of vent fluid Fe escapes precipitation as Fe sulfide as the vent fluids are expelled at the seabed and (ii) rapid conversion of Fe(II) to Fe(III) and precipitation of Fe-(oxyhydr)oxides in the buoyant plume. While our new data suggest that spreading rate therefore plays no obvious control on the Fe isotopic signature of dFe delivered to the neutrally buoyant plume, and potentially into the ocean interior, the effects of Fe-binding organic ligands on $\delta^{56}\text{Fe}$ as the plume evolves remain uncertain (*Toner et al., 2009; Fitzsimmons et al., 2017*). There is a clear need for additional studies that quantify the iron isotopic signatures of the truly dissolved (soluble) and colloidal iron fractions as well as longer term incubation experiments that also measure the strength and concentration of iron-binding ligands.

6 Conclusions

This study investigated the chemical processes that regulate the evolution of the iron isotopic signature of hydrothermal Fe during mixing between high-temperature vent fluids and seawater at the Beebe and the Von Damm vent fields on the Mid-Cayman ultraslow-spreading ridge. Hydrothermal vent fluids from Beebe had $\delta^{56}\text{Fe} = -0.28\text{‰}$, similar to other vent sites, whereas vent fluids from Von Damm had slightly higher $\delta^{56}\text{Fe}$ ($+0.08\text{‰}$), likely due to precipitation of Fe-sulfides that preferentially incorporate lighter Fe isotopes prior to venting at the seafloor. At Beebe, around 50% of hydrothermal Fe precipitates as Fe-sulfides as soon as the vent fluids are expelled at the seabed. Isotope data from incubation experiments on a Beebe buoyant plume sample indicate that nanoparticulate Fe-sulfides can be carried upwards into the Beebe buoyant plume, eventually coagulating and settling out over time.

At both sites, the $\delta^{56}\text{Fe}$ value of dFe in the early stages of buoyant plume formation was significantly lower than the $\delta^{56}\text{Fe}$ value of the vent fluids (or background seawater), reaching values of as low as -4.08‰ at Beebe and -2.49‰ at Von Damm. We show that this can be principally attributed to oxidation of Fe(II) and precipitation of the Fe-(oxyhydr)oxides that form. This is supported by analyses of the iron isotopic composition of TDFe; labile particulate Fe is isotopically heavy ($\delta^{56}\text{Fe} = -0.13$ to $+0.71\text{‰}$) compared to the dFe, suggesting that labile particulate Fe principally consists of Fe-(oxyhydr)oxides.

695 **Table 1** Composition of hydrothermal vent fluids from Beebe and Von Damm. NA = not
696 available; * calculated from all available data, which are given in the SI, except $\delta^{56}\text{Fe}$ which is
697 given as the value measured in the sample with lowest Mg. End-member uncertainty is the
698 computed standard error (1σ) on the Mg = 0 mM intercept (see text for details).

Fig. 1 Location of the Beebe and Von Damm vent fields (respectively, BVF and VDVF) on the Mid-Cayman spreading ridge. Map courtesy of <http://www.geomapapp.org>

Fig. 2 (a) Concentrations of dissolved Fe (dFe) and total dissolvable Fe (TDFe), relative to vent fluid (VF) dilution factor at Beebe and Von Damm vent fields. The dashed lines show conservative mixing of the end-member fluid with background seawater, for Beebe (red) and Von Damm (blue). **(b)** Fe isotope compositions of dFe and TDFe ($\delta^{56}\text{Fe}$ of dFe and TDFe), relative to vent fluid dilution factor at Beebe and Von Damm. The grey band represents $\delta^{56}\text{Fe}$ of the lowest Mg vent fluids from both sites (see Table 1). Data are provided in the Supplementary Information (Table S2).

(a) Fe isotope fractionation during Fe(II)-Fe(III) oxidation

(b) Fe isotope fractionation during Fe-sulfide precipitation

Fig. 3 (a) $\delta^{56}\text{Fe}$ relative to the fraction of dFe(II) oxidised to Fe(III). The observed $\delta^{56}\text{Fe}$ values of dFe in the earliest stages of buoyant plume formation at Beebe and Von Damm are consistent with a Rayleigh fractionation model with $\delta^{56}\text{Fe}(\text{III}) - \delta^{56}\text{Fe}(\text{II})_{\text{aq}} = 3.5\text{‰}$ (see text for details). The calculated $\delta^{56}\text{Fe}$ values of labile particulate Fe are generally consistent or slightly lower than predicted by the Rayleigh fractionation model. The horizontal error bars reflect the uncertainty in the proportion of dFe(II) in the dFe pool (0 to 100%). **(b)** $\delta^{56}\text{Fe}$ relative to the fraction of TDFe lost from the plume at Beebe. Solid line shows the evolution of $\delta^{56}\text{Fe}$ of TDFe predicted by Rayleigh fractionation modelling of sulfide precipitation (see text for details). The

724 horizontal error bars reflect the uncertainty in the composition of the end-member fluid ([Table](#)
725 [S2](#)).

726

Fig. 4 (a) Change in dFe and $\delta^{56}\text{Fe}$ of dFe in the buoyant plume with time since the sample bottle was closed at Beebe, and **(b)** at E2 (*Lough et al., 2017*) for comparison. **(c and d)** Variation in $\delta^{56}\text{Fe}$ of dFe as a function of the proportion of dFe removed from solution over the course of the incubation experiment. Solid line in **(c)** shows results of a mass balance model for coagulation of Fe-sulfide nanoparticles that are assumed to constitute ~75% of the dFe fraction and have a distinct $\delta^{56}\text{Fe}$ of -0.68‰ (see text and [Table S3](#) for details). Solid line in **(d)** shows results of a Rayleigh fractionation model for particle scavenging, $\delta^{56}\text{Fe}_{\text{scavenged}} - \delta^{56}\text{Fe}_{\text{dFe}} = -0.18$ to -0.30‰ (see text for details).

Fig. 5 Range of $\delta^{56}\text{Fe}$ values of dFe measured to date in hydrothermal plumes, compared to (a) vent fluid Fe/H₂S ratio and (b) Fe(II) half-life time. dFe isotope data are from: this study (Beebe and Von Damm); Conway and John (2014) (TAG on the Mid-Atlantic Ridge); Lough et al. (2017), Klar et al. (2017) (E2 and E9N on the East Scotia Ridge); Fitzsimmons et al. (2017) (15°S East Pacific Rise); Nasemann et al. (2018) (Nifonea at Vanuatu back-arc); Rouxel et al. (2018) (Pele's Pit at Loihi Seamount). Literature data, along with sources of vent fluid Fe/H₂S ratio and Fe(II) half-life, are given in the Supplementary Information (Table S5). Range in $\delta^{56}\text{Fe}$ of end-member hydrothermal fluids measured to date (Table S4) is shown by the vertical grey band.
