## ABSTRACT

We present six epochs of spectropolarimetric observations of the hot-Jupiter-hosting star  $\tau$  Boötis that extend the exceptional previous multiyear data set of its large-scale magnetic field. Our results confirm that the large-scale magnetic field of  $\tau$  Boötis varies cyclicly, with the observation of two further magnetic reversals; between 2013 December and 2014 May and between 2015 January and March. We also show that the field evolves in a broadly solar-type manner in contrast to other F-type stars. We further present new results which indicate that the chromospheric activity cycle and the magnetic activity cycles are related, which would indicate a very rapid magnetic cycle. As an exemplar of long-term magnetic field evolution,  $\tau$  Boötis and this long-term monitoring campaign presents a unique opportunity for studying stellar magnetic cycles.

**Key words:** magnetic fields – techniques: polarimetric – stars: activity – stars: imaging – stars: individual:  $\tau$  Boo – planetary systems.

## 1 INTRODUCTION

Magnetic fields of planet-hosting stars are of significant interest given the expected role of the magnetic field in both stellar and planetary system evolution.  $\tau$  Boötis (HR 5185, HD 120136, F7V, age  $\sim 1$  Gyr; list of stellar parameters given in Table 1) hosts a hot Jupiter with a mass of  $\sim 6M_{\text{Jupiter}}$  (Brogi et al. 2012; Rodler, Lopez-Morales & Ribas 2012; Borsa et al. 2015) orbiting at 0.049 au in approximately 3.31 d (Butler et al. 1997; Leigh et al. 2003; Borsa et al. 2015) and has been the subject of periodic observation of its magnetic field since 2007. This unique long-term spectropolarimetric observational series of  $\tau$  Boötis has allowed the investigation of the evolution of its magnetic topology over an extended period.

Donati et al. (2008) and Fares et al. (2009, 2013) have observed that  $\tau$  Boötis exhibits a magnetic cycle including polarity reversals occurring roughly on a yearly time-scale. Studies of younger stars which like  $\tau$  Boötis have shallow convective zones (Marsden et al. 2006; Jeffers & Donati 2008; Jeffers et al. 2011), have not shown magnetic cycles; perhaps because the duration of the cycles are longer than the periods of observation or because their cycles are irregular or chaotic. Fares et al. (2009) speculate that the hot Jupiter

with  $M_p \sim 6M_{\text{Jupiter}}$  (compared to the stellar convective envelope with a mass of  $\sim 0.5M_{\text{Jupiter}}$ ) may accelerate the stellar magnetic activity cycle by synchronizing the outer convective envelope of the star (due to tidal interactions) and enhancing the shear at the tachocline.

$\tau$  Boötis has been a target of interest for those searching for star–planet interaction (SPI). Photometric observations from the *MOST* satellite by Walker et al. (2008) suggested that a persistent active region exists on the star synchronized with the period of the hot Jupiter, but leading the subplanetary longitude by  $\sim 68^\circ$ . The presence of a persistent active region may suggest SPI. Lanza (2012) contends that models rule out that any such ‘hotspots’ are due to magnetic SPI, and therefore if truly related to the planetary period, they must be via some other mechanism. Given that the orbital period of the planet  $\tau$  Boötis b and the star’s rotational period are presumed to be synchronized, observations of the star may not resolve whether or not any rotationally modulated chromospheric features are indicative of SPI or not.

More recently, Borsa et al. (2015) analysed spectra of  $\tau$  Boötis using the HARPS-N spectrograph. Their study suggests that a high-latitude plage was present near one pole of the star. While Borsa et al. (2015) conclude that ‘it is unclear if it is due to SPI or to a corotating active region, or both’, this observation is particularly interesting as it overlaps with one of the epochs presented in this work and is discussed in the conclusion.

**Table 1.** Table of stellar parameters for  $\tau$  Boötis. [References: 1 = Borsa et al. (2015); 2 = Brogi et al. (2012)]

| Parameter        |                        | Value            | Reference |
|------------------|------------------------|------------------|-----------|
| $T_{\text{eff}}$ | (K)                    | $6399 \pm 45$    | 1         |
| $\log g$         | ( $\text{cm s}^{-1}$ ) | $4.27 \pm 0.06$  | 1         |
| [Fe/H]           |                        | $0.26 \pm 0.03$  | 1         |
| $v \sin i$       | ( $\text{km s}^{-1}$ ) | $14.27 \pm 0.06$ | 1         |
| Luminosity       | ( $L_{\odot}$ )        | $3.06 \pm 0.16$  | 1         |
| Mass             | ( $M_{\odot}$ )        | $1.39 \pm 0.25$  | 1         |
| Radius           | ( $R_{\odot}$ )        | $1.42 \pm 0.08$  | 1         |
| Age              | (Gyr)                  | $0.9 \pm 0.5$    | 1         |
| Inclination      | ( $^{\circ}$ )         | $44.5 \pm 1.5$   | 2         |

We present in this paper a new set of epochs to extend the spectropolarimetric study of  $\tau$  Boötis as part of the BCool collaboration<sup>1</sup> on the magnetic fields of cool stars. Radial magnetic maps from previous epochs of observation have been used as boundary conditions for modelling the wind environment around the star (Vidotto et al. 2012). Similarly, work presented here provides these boundary conditions for an ongoing monitoring of the stellar wind of  $\tau$  Boötis (Nicholson et al. 2016).

Investigation of the Ca II H&K stellar activity proxy of the star is shown in Section 3. Modelling of the large-scale magnetic field of the star, including its differential rotation is presented in Section 4. We draw conclusions in Section 5.

## 2 OBSERVATIONS AND DATA PROCESSING

Stokes V spectropolarimetric data of  $\tau$  Boötis were obtained in 2011 May using the HARPS polarimeter (hereafter, referred to as HARPSpol) and in 2013–2015, using the NARVAL high-resolution spectropolarimeter. Each Stokes V spectrum is derived from a sequence of four subexposures taken with the waveplates (HARPSpol)/retarder rhombs (NARVAL) of the polarimeters in different positions (Semel, Donati & Rees 1993; Donati et al. 1997). The phases of the data are derived using the same orbital ephemeris as that used by Catala et al. (2007), Donati et al. (2008) and Fares et al. (2009, 2013):

$$T_0 = \text{HJD } 2453450.984 + 3.31245 E, \quad (1)$$

with phase 0.0 denoting the first conjunction (i.e. the planet furthest from the observer).

### 2.1 Observations with HARPSpol

HARPSpol (Piskunov et al. 2011) is located at the ESO 3.6-m telescope at La Silla. HARPSpol has a spectral resolution of around 110 000, with spectral coverage from 380 to 690 nm. In 2011 May, 18 spectra were collected over six nights using HARPSpol, providing good coverage of the complete rotational cycle. The journal of observations from 2011 May is shown in Table B1.

### 2.2 Observations with NARVAL

NARVAL is attached to the 2-m Telescope Bernard Lyot (TBL) at Pic du Midi. A twin of the CFHT ESPaDOnS instrument (Donati 2003), NARVAL has a spectral coverage of 370–1048 nm with a

resolution of approximately 65 000. Information on NARVAL can be found in Aurière (2003).

From 2013 April 23 until May 13 (approximately 21 nights), eight observations were taken using NARVAL. The coverage of the stellar cycle was incomplete, with two observations close to  $\phi_{\text{rot}} \sim 0.25$  and the remaining six giving relatively even coverage of  $0.5 < \phi_{\text{rot}} < 1$ . 12 observations were taken using NARVAL from 2013 December 4 until December 21 (17 nights). The coverage of the stellar surface was sparse but relatively complete. 11 observations were taken using NARVAL between 2014 May 4 and May 18 (14 nights). In 2015 January, seven observations were obtained using NARVAL over 12 nights. The journal of observations from 2013 April through 2015 January is shown in Table B2.

Beginning in 2015 March, a further series of observations of  $\tau$  Boötis were obtained. The observations were more sparsely separated and spanned a significant period of time ( $\sim 70$  d,  $\sim 22$  rotations). Given that this period is considered too long for a single Zeeman Doppler Imaging (ZDI) analysis due to potential for feature evolution, this data set was divided into multiple overlapping epochs and analysed separately. Thus, this observational data is presented in its own journal of observations (Table B3).

### 2.3 Data reduction

Data from NARVAL was automatically reduced using the LIBRE-ESPRIT software package. A specifically modified version of LIBRE-ESPRIT was used by J.-F. Donati to reduce the data from HARPSpol. LIBRE-ESPRIT produces Stokes I (unpolarized) and Stokes V (circularly polarized) spectra, in addition to a null (N) spectrum which is used to determine the authenticity of a detected polarization signal (Donati et al. 1997).

#### 2.3.1 Least-squares deconvolution (LSD)

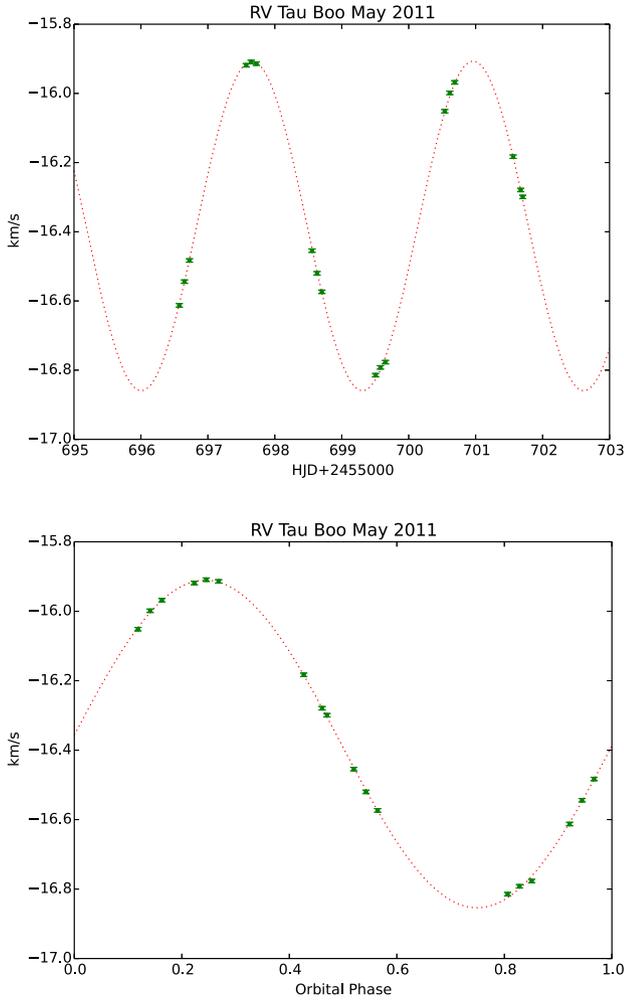

As Zeeman signatures are typically smaller than the noise level within a single spectral line, they are difficult to detect, especially for solar-type stars such as  $\tau$  Boötis. The LSD technique is applied to improve the S/N of the data by combining the information provided by many spectral lines (Donati et al. 1997). The line mask used to perform the deconvolution is the same as described in Donati et al. (2008) and Fares et al. (2009), using a Kurucz model atmosphere with solar abundances, an effective temperature of 6250 K and  $\log g$  of  $4.0 \text{ cm s}^{-1}$ , including most strong lines in the optical domain (central depths  $> \sim 40$  per cent of the local continuum before macroturbulent or rotational broadening) but excluding the strongest, broadest features such as Balmer lines. This results in each deconvolution utilizing 3000–4000 lines, depending on the particular spectral coverage of the instrument.

In the journals of observations (Tables B1–B3), a definite detection (D) in the LSD Stokes V profile is defined as a false alarm probability (*fap*) of less than  $10^{-5}$ . A marginal detection (M) has a false alarm probability greater than  $10^{-5}$  but less than  $10^{-3}$  (Donati et al. 1997).

#### 2.3.2 Radial velocity

Due to the presence of the hot Jupiter in orbit around  $\tau$  Boötis, the radial velocity (RV) of the star varies from observation to observation. The best-fitting semi-amplitude of  $476 \text{ m s}^{-1}$  we derive is close to that found by Butler et al. (1997) and in good agreement with the expected phasing using the orbital ephemeris of (Catala

<sup>1</sup> <http://bcool.ast.obs-mip.fr>

**Figure 1.** Radial velocity of  $\tau$  Boötis, 2011 May derived from HARPSpol data as a function of HJD (upper panel) and as a function of orbital phase (lower panel). The errors in the measurements are  $\sim 5 \text{ m s}^{-1}$ , which is the approximate error for HARPSpol in pure spectroscopic mode (Mayor et al. (2003) and the accompanying HARPS performance summary<sup>2</sup>). The fitted semi-amplitude of  $476 \text{ m s}^{-1}$  is close to that in Butler et al. (1997).

et al. 2007, see Fig. 1 for 2011 May observations). The spectra are automatically corrected by the LIBRE-ESPRIT software for RV variations due to the motion of the Earth. The RV of the star due to the orbital motion of the system is derived by fitting the Stokes I LSD profile of each observation with a Gaussian and determining the centre of the profile. The spectra are then corrected for the RV due to the system’s orbital motion.

### 3 Ca II H&K ACTIVITY PROXY

The emission in the cores of the Ca II H&K lines is one of the most widely used proxies for stellar chromospheric activity. The S-index for each observation of  $\tau$  Boötis was calculated using the method

**Table 2.** Table of coefficients for equation (2) as calculated by Marsden et al. (2014) for the NARVAL instrument.

| Coefficient | NARVAL                 |
|-------------|------------------------|
| $a$         | 12.873                 |
| $b$         | 2.502                  |
| $c$         | 8.877                  |
| $d$         | 4.271                  |
| $e$         | $1.183 \times 10^{-3}$ |

of Wright et al. (2004) and utilizing the coefficients for NARVAL derived by Marsden et al. (2014) for the equation:

$$\text{S-index} = \text{Ca}_{\text{HK}}\text{-index} = \frac{aF_{\text{H}} + bF_{\text{K}}}{cF_{R_{\text{HK}}} + dF_{V_{\text{HK}}}} + e, \quad (2)$$

where  $F_{\text{H}}$  and  $F_{\text{K}}$  are the fluxes in a  $2.18\text{\AA}$  triangular bandpasses centred on the cores of the Ca II H&K lines,  $F_{R_{\text{HK}}}$  and  $F_{V_{\text{HK}}}$  are rectangular  $20\text{\AA}$  bandpasses centred on the continuum at  $3901.07$  and  $4001.07\text{\AA}$  (Wright et al. 2004, fig. 1). These coefficients for the NARVAL instrument are shown in Table 2.

Following the methodology of Marsden et al. (2014), overlapping orders were removed from the reduced spectra of  $\tau$  Boötis and adjusted for the RV for the observation. In addition to the newly observed epochs, all prior observations of  $\tau$  Boötis with the NARVAL instrument were retrieved from the Polarbase<sup>3</sup> (Petit et al. 2014) data base, and we calculated values of the S-index for each normalized individual exposure of  $\tau$  Boötis, making four data points for each spectropolarimetric sequence. These are shown in Fig. 2. As noted in Fares et al. (2009),  $\tau$  Boötis exhibits intrinsic variability through each night and night to night, and this can be observed in the data. Using a least-squares fit of a sinusoid to the unweighted S-index data, we find a longer term variability in chromospheric activity of  $\sim 117$  d. This result corresponds well to the  $\sim 116$  d period reported by Baliunas et al. (1997) and Henry et al. (2000) from the Mount Wilson HK project (Baliunas et al. 1998).

There also appears to be a longer term trend apparent in the data. Baliunas et al. (1997) reports a low-amplitude 11.6 yr activity cycle, however our data set is too short to reliably perform a fit of that duration. In attempting to fit multiple periods, various results converged depending upon initial conditions. There are several fits of equally good quality with different periodicities from approximately  $\sim 300$  d to several thousand days and given the large gaps in the observational records, these periods are uncertain. Further observational epochs taken at shorter intervals are required to accurately characterize the cyclic behaviour of the Ca II H&K activity proxy of  $\tau$  Boötis and if any relationship to other observed cycles exists.

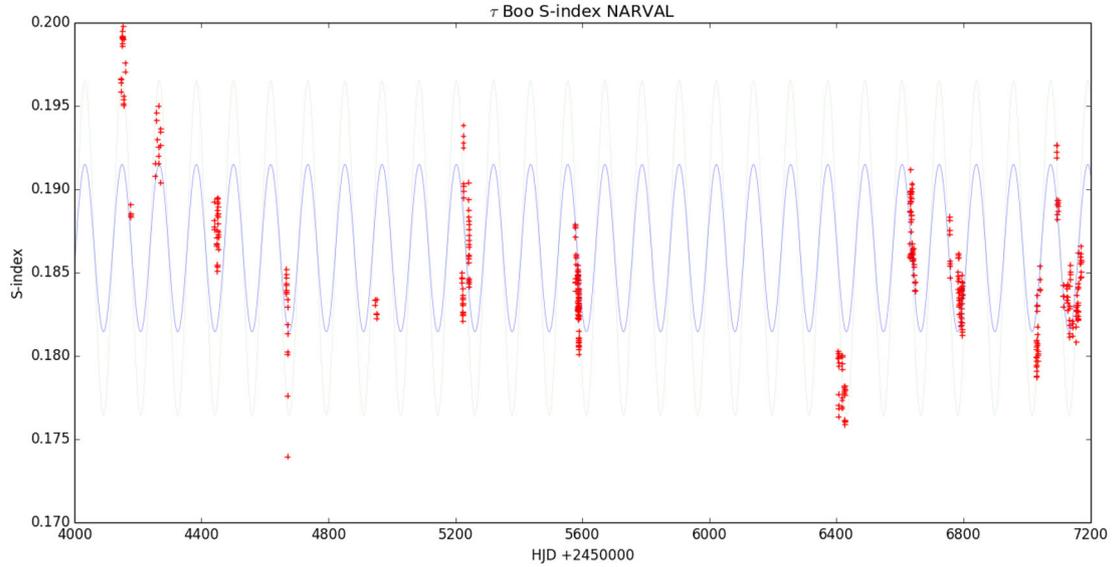

## 4 MAGNETIC MAPPING

### 4.1 Model description

ZDI is used to reconstruct maps of the magnetic topology of  $\tau$  Boötis from the observed Stokes V signatures. The process uses the principles of maximum entropy image reconstruction to produce the configuration of the large-scale magnetic field containing the minimum information required to produce the observed magnetic signatures. The code used is that described in Donati et al. (2006)

<sup>2</sup> <http://www.eso.org/sci/facilities/lasilla/instruments/harps/inst/performance.html>

<sup>3</sup> <http://polarbase.irap.omp.eu/>

**Figure 2.** Ca II H&K S-indices for  $\tau$  Boötis. NARVAL observations are shown in red. A least-squares fit of a sinusoid to the unweighted data (blue line) yields a period of  $\sim 117$  d, which corresponds closely to the  $\sim 116$  d period reported by Baliunas et al. (1997) and Henry et al. (2000).

wherein spherical-harmonic expansions are used to describe the field configuration with respect to its poloidal and toroidal components. An advantage of this method is that the coefficients of the spherical harmonics can be used to calculate the energy contained in, for example, axisymmetric and non-axisymmetric modes, and to determine relative contributions of dipolar, quadrupolar and higher order components.

The stellar surface is divided into units of similar projected area and the contribution of each unit area to the Stokes V profile (based on field strength, orientation, surface location and motion) is calculated. The process continues iteratively wherein profiles are reconstructed and compared to the observed profiles until a match within the desired error is reached (typically a unit reduced  $\chi^2$ ; i.e.  $\chi_r^2 \sim 1$ ).

The local Stokes I profile is modelled by a Gaussian [full width at half-maximum (FWHM) of  $11 \text{ km s}^{-1}$ ], while the local Stokes V is calculated assuming the weak field approximation (Donati et al. 1997):

$$V \propto g B_{\text{los}} \frac{dI}{dv}, \quad (3)$$

where  $B_{\text{los}}$  is the local line-of-sight component of the magnetic field and  $g$  is the mean Landé factor.

## 4.2 Differential rotation

### 4.2.1 Method

When a star is differentially rotating, the signatures produced by magnetic regions will repeat from rotational cycle to rotational cycle but with differences resulting from shifts in the relative location of the regions due to the differential rotation. We consider that the rotation will follow a simplified solar-type law:

$$\Omega(\theta) = \Omega_{\text{eq}} - d\Omega \sin^2 \theta, \quad (4)$$

where  $\Omega(\theta)$  is the rotation rate of the star at latitude  $\theta$  in  $\text{rad d}^{-1}$ ,  $\Omega_{\text{eq}}$  is the rotation rate at the equator and  $d\Omega$  is the rotational shear between the equator and the poles.

Applying the method described by Donati et al. (2000), Petit, Donati & Collier-Cameron (2002), Donati, Cameron & Petit (2003) and Morin et al. (2008), we construct a magnetic image containing a given information content for each pair of  $(\Omega_{\text{eq}}, d\Omega)$  and choose the pair of parameters which produces the best fit to the data (i.e. the smallest  $\chi_r^2$ ). An example for the 2013 December data set is shown in Fig. 3(a). Fig. 3(b) shows how we derive  $\sim 1\sigma$  variation bars as a measure of uncertainty by varying various stellar parameters ( $v \sin i \pm 1 \text{ km s}^{-1}$ ; inclination  $\pm 10^\circ$ ; target reconstructed average magnetic field  $B_{\text{mod}} \pm \sim 10$  per cent) and calculating the extreme variations.

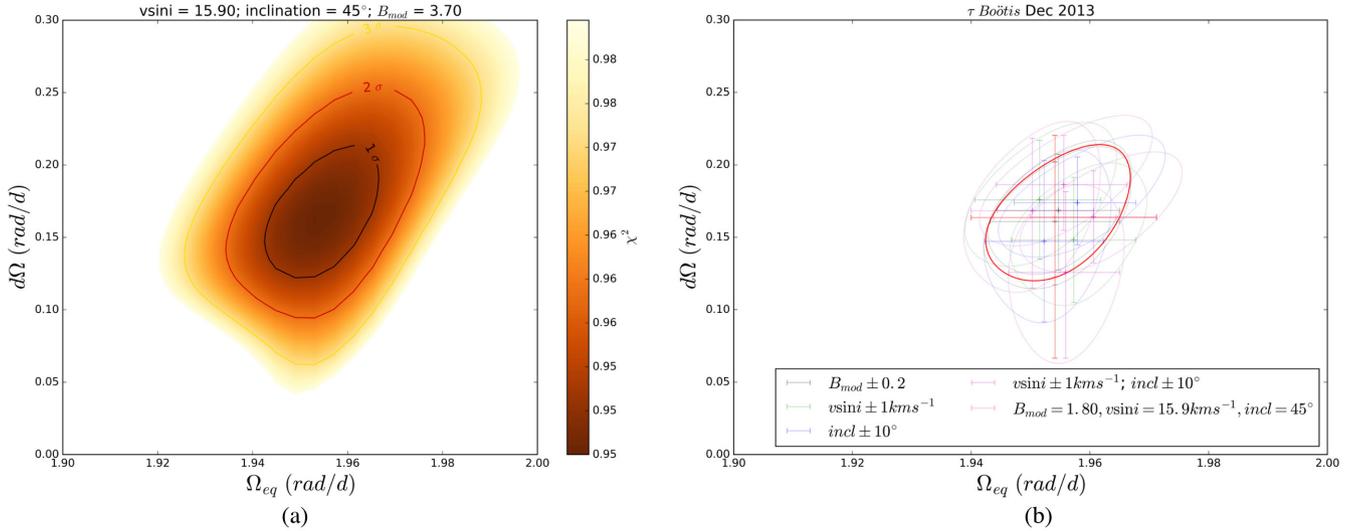

Donati et al. (2008) measured the differential rotation of  $\tau$  Boötis utilizing the Stokes V data, equal to  $\Omega_{\text{eq}} = 2.10 \pm 0.04 \text{ rad d}^{-1}$  and  $d\Omega = 0.50 \pm 0.12 \text{ rad d}^{-1}$ . However, subsequent observations have yielded either different values of  $\Omega_{\text{eq}}$  and  $d\Omega$  [e.g. 2008 January,  $d\Omega = 0.28 \pm 0.10$ ; Fares et al. (2009)] or no measurement has been possible (Fares et al. 2013).

### 4.2.2 Results

The 2011 May HARPSpol data produced a well-defined paraboloid, albeit with a larger error compared to other runs. The HARPSpol data are of a lower S/N than that from NARVAL, however, the 2011 May phase coverage is superior to the other runs. The derived parameters of  $\Omega_{\text{eq}} = 2.03_{-0.05}^{+0.05}$  and  $d\Omega = 0.42_{-0.11}^{+0.11} \text{ rad d}^{-1}$  is consistent with those of Donati et al. (2008).

For the NARVAL data from 2013 April/May, we measure a significant error bar. The maps for 2013 April and May show that there are only two observations of the star consistent with phase  $\sim 0.25$  ( $\phi_{\text{rot}}$  of  $-2.749$  and  $+3.262$ ), and these are separated by  $\sim 6$  full rotations ( $\sim 20$  d). Removing these observations results in a smaller error and a lower value of  $d\Omega$ . However, the DR measurement used in our mapping and reported in Table 3 is made with all observations present, hence a much larger error is calculated. The derived parameters for 2013 April/May were  $\Omega_{\text{eq}} = 2.05_{-0.04}^{+0.04}$  and  $d\Omega = 0.38_{-0.19}^{+0.18} \text{ rad d}^{-1}$ .

With a better coverage of the stellar rotational cycle in 2013 December, a clear paraboloid was again generated (Fig. 3a). The

**Figure 3.** Differential rotation of  $\tau$  Boötis for 2013 December. Panel (a) shows the variation of  $\chi_r^2$  as a function of  $\Omega_{\text{eq}}$  and  $d\Omega$  for the selected stellar parameters ( $v \sin i = 15.9 \text{ km s}^{-1}$ , inclination  $45^\circ$ ) and a target  $B_{\text{mod}}$  appropriate for the desired  $\chi_r^2$  used to reconstruct the magnetic maps of this epoch. Panel (b) shows second-order polynomial fits for the  $1\sigma$  threshold paraboloids surrounding the minimum  $\chi_r^2$ , where the red paraboloid corresponds to the plot in panel (a). Other paraboloids represent fits to the corresponding DR calculations varying the target  $B_{\text{mod}}$  ( $\pm \sim 10$  per cent, black),  $v \sin i$  ( $\pm 1 \text{ km s}^{-1}$ ) and stellar inclination ( $\pm 10^\circ$ ) independently (green and blue) and  $v \sin i$  and inclination angle together (magenta). The overall variation bars are used to derive the uncertainty in the measured DR parameters.

**Table 3.** Summary of differential rotation parameters for  $\tau$  Boötis as measured by the  $\chi^2$  minimization method. For comparison, the FT method (Sec. 4.2.4, assuming  $\Omega_{\text{eq}} = 2.00 \text{ rad d}^{-1}$ ) yields  $d\Omega = 0.35 \pm 0.14 \text{ rad d}^{-1}$ . The values presented below are used in the magnetic mapping.

| Epoch          | $\Omega_{\text{eq}}$<br>( $\text{rad d}^{-1}$ ) | $d\Omega$<br>( $\text{rad d}^{-1}$ ) |
|----------------|---|--------------------------------------|
| 2011 May       | $2.03^{+0.05}_{-0.05}$                          | $0.42^{+0.11}_{-0.11}$               |
| 2013 April/May | $2.05^{+0.04}_{-0.04}$                          | $0.38^{+0.18}_{-0.19}$               |
| 2013 December  | $1.95^{+0.01}_{-0.01}$                          | $0.16^{+0.04}_{-0.04}$               |
| 2014 May       | $1.99^{+0.01}_{-0.01}$                          | $0.10^{+0.04}_{-0.04}$               |
| 2015 January   | $1.98^{+0.03}_{-0.03}$                          | $0.15^{+0.15}_{-0.16}$               |

measured differential rotation for 2013 December corresponded to parameters of  $\Omega_{\text{eq}} = 1.95^{+0.01}_{-0.01} \text{ rad d}^{-1}$  and  $d\Omega = 0.16^{+0.04}_{-0.04} \text{ rad d}^{-1}$ .

The data for 2014 May once more produced a clear paraboloid with the parameters  $\Omega_{\text{eq}} = 1.99^{+0.01}_{-0.01} \text{ rad d}^{-1}$  and  $d\Omega = 0.10^{+0.04}_{-0.04} \text{ rad d}^{-1}$ . Finally, the derived parameters for 2015 January were  $\Omega_{\text{eq}} = 1.98^{+0.03}_{-0.03} \text{ rad d}^{-1}$  and  $d\Omega = 0.15^{+0.15}_{-0.16} \text{ rad d}^{-1}$ .

These values are summarized in Table 3.

#### 4.2.3 A discussion of variable differential rotation measurement

Table 3 makes clear that the technique used to determine differential rotation yields a wide variation in  $d\Omega$ , but is consistent with solar-like differential rotation with the equator rotating faster than the poles.  $\Omega_{\text{eq}}$  is much more constrained within a range from  $\sim 1.95$  to  $2.05 \text{ rad d}^{-1}$ , ignoring the error. As simulations performed by Petit et al. (2002) show, factors including the phase coverage and observational cadence can have significant effects on the measured differential rotation parameters.

Notably, apart from the 2011 May HARPSpol observation, at best the observations of  $\tau$  Boötis have had a single observation per night (approximately one  $4 \times 600 \text{ s}$  observation every one-third of

a rotation) over several full stellar rotations. As the technique used to determine differential rotation is a  $\chi^2$ -landscape technique and dependent upon the regular re-observation of features, it is possible that the significant variation in the measured parameters are due to observational biases. The weakness of the field of  $\tau$  Boötis and the difficulty in observing Zeeman signatures on the star potentially exacerbates this effect. Attempting the  $\chi^2$  minimization method with lower values of target  $B_{\text{mod}}$  with various  $\tau$  Boötis data sets, (corresponding to higher  $\chi_r^2$  fits) thus providing less information for the technique produces a systemic decrease in the calculated values of  $\Omega_{\text{eq}}$  and  $d\Omega$ .

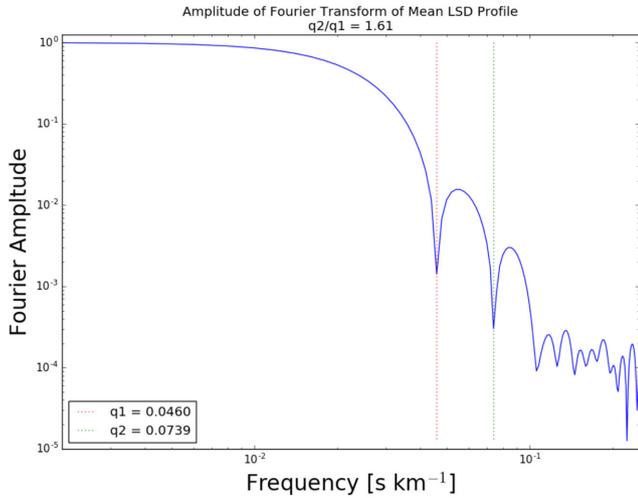

This supposition would need to be confirmed by simulations and it should be noted that this does not rule out the existence of small or significant actual variation in differential rotation of magnetic features on  $\tau$  Boötis; simply that we cannot draw any such conclusion from these measurements. A paper is in preparation (Mengel et al.) examining the effect of phase coverage on measuring DR parameters on slow rotating weak-field stars and how we may determine optimal observational cadences and periods for this type of target.

Finally, it is to be noted that varying  $d\Omega$  will slightly distort the shape of the features on the maps but does not appear to have a significant effect in the determination of the general magnetic field properties (Table 6). Consequently to be internally consistent in applying the maximum-entropy, minimum information mapping technique, these measured values for  $d\Omega$  and  $\Omega_{\text{eq}}$  which give the minimum information solution have been utilized in the magnetic mapping in this work.

#### 4.2.4 Stokes I differential rotation – Fourier transform method

An alternative measurement of the differential rotation can be made using the Fourier transform (FT) method described by Reiners & Schmitt (2003).

An averaged Stokes I profile was created from the NARVAL and HARPSpol data for each observational epoch. Using the method of

**Figure 4.** Amplitude of the Fourier transform of the averaged LSD Stokes I profile for 2014 May. The first two zeros ( $q_1$ ,  $q_2$ ) are shown. The ratio  $q_2/q_1$  can be used to derive  $\alpha$  ( $d\Omega/\Omega_{\text{eq}}$ ) as described in the text (Section 4.2.4).

Reiners & Schmitt (2003), we obtained the ratio of the first two zeros of the Fourier-transformed average Stokes I line profile ( $q_2/q_1$ ). An example of this is shown for the 2014 May epoch in Fig. 4. For each epoch, we determined that  $q_2/q_1 = 1.61 \pm 0.07$ . From equation 5 in Reiners & Schmitt (2003), using an inclination angle of  $45^\circ$ , we thus calculate  $\alpha$  ( $d\Omega/\Omega_{\text{eq}}$ ) of  $\approx 0.17$ .

Using the various measured values of  $\Omega_{\text{eq}}$  from Table 3, this produces a value for  $d\Omega$  of between  $0.34$  and  $0.36 \text{ rad d}^{-1}$ , which is in good agreement with the value found by Reiners (2006), Catala et al. (2007), and Borsa et al. (2015) for  $\tau$  Boötis.

It is noted that this technique is quite sensitive to the derived value of  $q_2/q_1$ . Thus using  $q_2/q_1 = 1.61 \pm 0.07$  would yield an uncertainty in  $d\Omega$  of  $0.14 \text{ rad d}^{-1}$ . Again, this uncertainty is in agreement with the measurements of the differential rotation of  $\tau$  Boötis by Reiners (2006).

Yielding a value of  $d\Omega = 0.35 \pm 0.14 \text{ rad d}^{-1}$ , the Fourier transform method is broadly consistent with the values derived by the  $\chi^2$ -landscape method taking into account the errors calculated for both methods. Despite the consistency of the two methods described here, the differential rotation measurement must be viewed with caution due to the uncertainties and assumptions inherent in each method.

### 4.3 Magnetic mapping

#### 4.3.1 Stellar and model parameters

Utilizing the measured differential rotation parameters, a  $\chi^2$  minimization process was used to determine the optimum angle of inclination and  $v \sin i$ . The values derived were close to those used in previously published works (Fares et al. 2009, 2013) so an inclination of  $45^\circ$  and  $v \sin i$  of  $15.9 \text{ km s}^{-1}$  as used in Fares et al. (2013) were chosen and applied to all data sets. (It is noted that this value of  $v \sin i$  varies by  $\sim 10$  per cent from the latest published value shown in Table 1, however, the difference in the models was insignificant using either value, thus we use the derived value for consistency with previous works).

Once the stellar parameters and differential rotation values were chosen, maps were generated for different values of  $\chi_r^2$ .

The reconstructed average magnetic field ( $B_{\text{mod}}$ ) begins to rise significantly with a lower target  $\chi_r^2$  as the process begins fitting inappropriately to the noise inherent in the signatures, this requires the target  $\chi_r^2$  to be chosen with care. This effect is much more pronounced in the HARPSpol data than for the NARVAL data and it would thus be inappropriate to utilize the same  $\chi_r^2$  for the 2011 May data. Thus, a  $\chi_r^2$  was chosen to be 0.95 for the NARVAL data, and 1.10 for the HARPSpol data. A potential drawback of this is that the comparison of the absolute magnitude of the field strength may no longer be appropriate for the data sets derived from the different instruments or between data sets using the same instrument with significantly different S/N levels and thus target  $\chi_r^2$ .

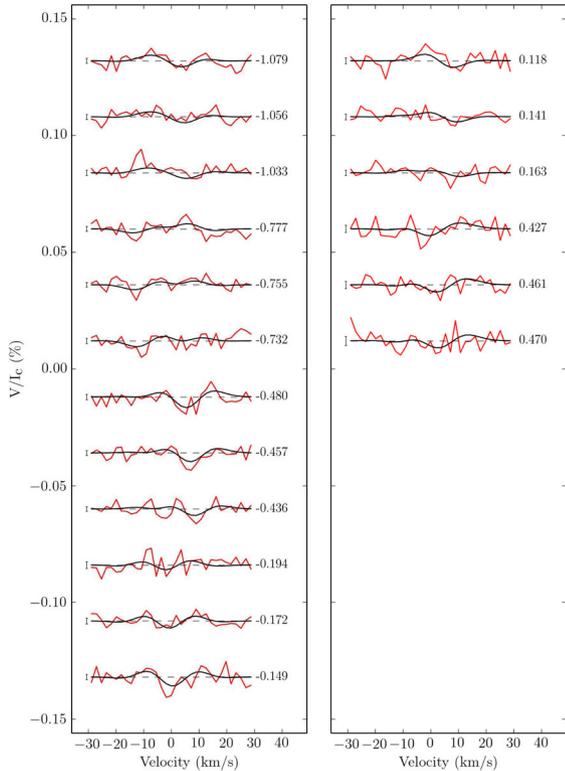

The spherical harmonic expansions for the reconstructed magnetic models were calculated using  $\ell = 8$  as little improvement was obtained using  $\ell > 8$ , there being near to zero energy in higher order harmonics. This is consistent with previous papers dealing with  $\tau$  Boötis and adequate given there are  $\sim 9$  spatial resolution elements around the equator as per equation (5) (Morin et al. 2010, equation 3).

$$\frac{2\pi v_e \sin i}{\text{FWHM}} = \frac{2\pi(15.9 \text{ km s}^{-1})}{11 \text{ km s}^{-1}} \sim 9 \quad (5)$$

The amount of energy in the various harmonics can be used to describe the configuration of the magnetic field (Donati et al. 2006). These results shown in Table 6 consist of three calculations. First, the amount of the magnetic energy stored in the toroidal component of the field is found from the  $\gamma_{\ell, m}$  term of the complex coefficients of the spherical harmonics. Secondly, the amount of magnetic energy in the poloidal component ( $\alpha_{\ell, m}$  and  $\beta_{\ell, m}$ ) which is axisymmetric (i.e. symmetric about the axis of rotation) is found from the  $\alpha_{\ell, m}$  and  $\beta_{\ell, m}$  coefficients of the spherical harmonics where  $m = 0$ . [Other papers, such as Fares et al. (2009, 2013) use  $m < \ell/2$  rather than  $m = 0$ . We consider  $m = 0$  to be more mathematically correct; however, the difference in practice is quite small so direct comparisons between epochs are possible. Where appropriate, this is noted in the text.] Finally, the amount of magnetic energy in the poloidal component of the magnetic field consisting of dipolar plus quadrupolar components is calculated from  $\alpha_{\ell, m}$  and  $\beta_{\ell, m}$  coefficients where  $\ell \leq 2$ .

As in the differential rotation measurements, an indication of the variation in these values is found by varying the differential rotation measurement by the error found for each epoch (holding inclination and  $v \sin i$  constant), then varying the stellar parameters (inclination  $\pm 10^\circ$ ;  $v \sin i \pm 1.0 \text{ km s}^{-1}$ ) while holding  $d\Omega$  and  $\Omega_{\text{eq}}$  constant. It is noted that the variation of stellar parameters produces variation in field components in a consistent way across the epochs, and the variations, although sometimes large relative to the values, are of the same order of magnitude across the epochs. The amount of toroidal field has the smallest variation due to parameter variation. The amount of energy in axisymmetric and  $\ell \leq 2$  modes in the poloidal field exhibit large variability with chosen stellar parameters, albeit with the dominant parameter affecting this variation being the chosen angle of inclination. Where there is a large uncertainty in the measured ( $d\Omega$ ,  $\Omega_{\text{eq}}$ ), such as in the 2011 May and 2015 January epochs, the combination of parameters can create significant variation.

As a derived inclination angle for  $\tau$  Boötis which is very close to our chosen value with a low level of uncertainty is known [cf.  $44.5^\circ \pm 1.5^\circ$  (Brogi et al. 2012) versus  $45^\circ$ ], the variation of inclination in our process by  $\pm 10^\circ$  is somewhat conservative and thus our variation values may be overestimated. Consequently, we have a reasonable confidence that epoch-to-epoch changes in

**Figure 5.** Circular polarization profiles of  $\tau$  Boo for HARPSpol observations, 2011 May. The observed profiles are shown in red, while synthetic profiles are shown in black. On the left of each profile, we show a  $\pm 1\sigma$  error bar. The rotational cycle of each observation is indicated on the right of each profile. All images of profile fits such as this are on the same scale across this work.

the field topology are real irrespective of the sometimes large and conservative variation measurements.

As with determining differential rotation, phase coverage must be adequate to successfully reconstruct the features on the stellar surface. Features, and thus energy in the harmonics, may be missed if parts of the stellar surface are not observed. It is noted that the cadence observations of  $\tau$  Boötis in observations after 2011 is lower than previous epochs. Consequently, fewer phases are used in most of the epochs in this work compared to those of Donati et al. (2008) and Fares et al. (2009, 2013). Reconstruction of maps in this work with partial, sampled data sets shows that the latitude information of features and the overall field configurations seem to be conserved, albeit with a reduction in the overall energy seen in the harmonics. These effects for a star with a weak magnetic field was discussed briefly by Fares et al. (2012) and is being further investigated in a forthcoming paper from Mengel et al.

#### 4.3.2 Results – HARPSpol – 2011 May

Fig. 5 shows the observed and reconstructed profiles for 2011 May. Compared to the other epochs presented in this work, the magnetic signature is very small, and the observed profiles (in red) are relatively noisy, thus the reconstructed profiles begin fitting to the noise at a relatively high  $\chi_r^2$ . While HARPSpol has a higher resolution than NARVAL (110 000 cf. 65 000), the spectral coverage is smaller and consequently there are significantly fewer spectral lines to use in LSD. Nevertheless we observe, as per Fares et al. (2009), Fares et al. (2013), and Donati et al. (2008), that a weak magnetic field

is manifest on the surface of  $\tau$  Boötis in the order of 5–10 G. The magnetic topology for 2011 May is shown in Fig. 7, top row. This topology was reconstructed with  $\chi_r^2 = 1.10$ .

The magnetic field has evolved in configuration from the 2011 January observation presented in Fares et al. (2013). The mean field is somewhat weaker at 2.2 G (although as noted before, a direct comparison of the HARPSpol  $B_{\text{mod}}$  may be of limited utility given the differences in the  $\chi_r^2$ ), and the percentage of the toroidal component of the field has remained around the same (from 18 to 20 per cent). In addition, the field configuration has become more complex, with 19 per cent ( $m = 0$ ; value is  $\sim 25$  per cent if using  $m = \ell/2$ ) of the poloidal component in an axisymmetric configuration compared to 37 per cent, and only 26 per cent of the poloidal component contained in modes  $\ell \leq 2$  compared with 35 per cent.

#### 4.3.3 Results – NARVAL – 2013 April/May through 2015 January

Over a period from 2013 April until 2015 January, four epochs of  $\tau$  Boötis were observed using NARVAL at TBL. The reconstructed (black) and observed (red) magnetic profiles for these epochs are shown in Figs 6(a)–(d). In all four epochs, magnetic signatures are clearly observed, and the evolution of the signatures with rotation is clear.

All three sets of maps were reconstructed using the same inclination and  $v \sin i$  parameters and  $\chi_r^2 = 0.95$ . The values of the differential rotation parameters ( $\Omega_{\text{eq}}$ ,  $d\Omega$ ) as derived in Section 4.2 for each epoch were used for each reconstruction.

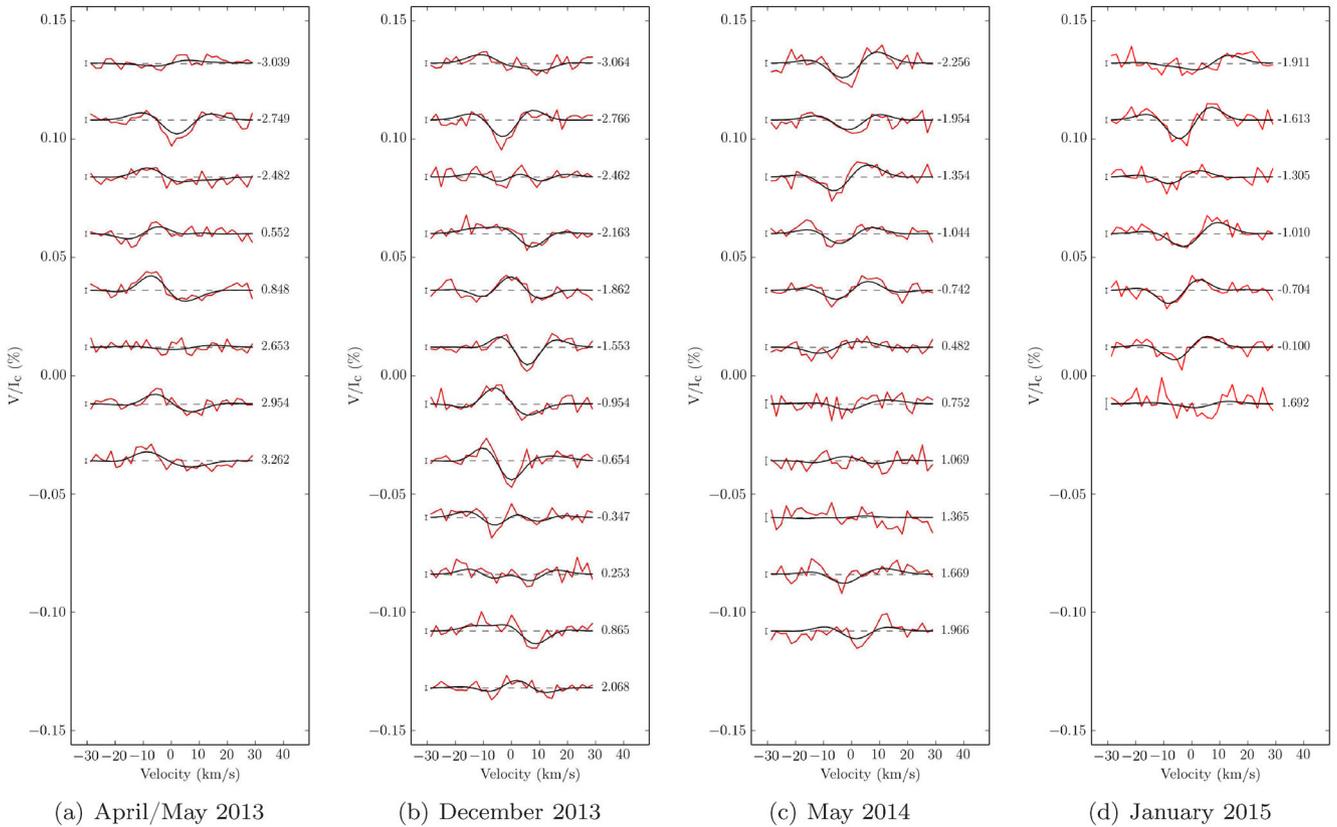

It is clear from the maps (Fig. 7, second, third, fourth and bottom rows) and from the parameters of the magnetic topology that the large-scale magnetic field on  $\tau$  Boötis evolved significantly over the 18 month period.

Between 2013 April/May and December, the field strength increased, and there was a negligible increase in the percentage of the calculated toroidal component. The amount of poloidal axisymmetry and the amount of field with modes of  $\ell \leq 2$  decreased (Table 6). In short, the field increased slightly in complexity.

Between 2013 December and 2014 May, a significant change occurred with a clear reversal of polarity in the radial field, coincident with a significant decrease in the percentage of the toroidal component (24 per cent to 13 per cent), an increase in the axisymmetric poloidal component (30 per cent to 46 per cent) and a slight increase (40 per cent to 45 per cent) in the amount of the poloidal field with modes of  $\ell \leq 2$ . After the reversal, the field became more poloidal and symmetric.

Between 2014 May and 2015 January as the next polarity reversal (expected between 2015 January and May) approached, the toroidal component of the field once more increased (from 12 per cent to 30 per cent), the axisymmetric component of the poloidal field dropped from 46 per cent to 37 per cent and the percentage of poloidal field in modes  $\ell \leq 2$  decreased slightly from 45 to 41. This represents another increase in the complexity of the field as the radial field reversal approaches.

There have now been three sets of sequential epochs of  $\tau$  Boötis observations which fall between radial field reversals. The latest two epoch pairs (2013 April/May and December; 2014 May and 2015 January) presented in this work show an increase in field strength and complexity between the reversals based on the amount of poloidal axisymmetric modes, modes with  $\ell \leq 2$  and an increase in toroidal field. The other inter-reversal epoch pair (2009 May/2010 January; Fares et al. 2013) of epochs showed an increase in field

**Figure 6.** Circular polarization profiles of  $\tau$  Boo for NARVAL observations, 2013 April through 2015 January. The observed profiles are shown in red, while synthetic profiles are shown in black. On the left of each profile, we show a  $\pm 1\sigma$  error bar. The rotational cycle of each observation is indicated on the right of each profile.

strength and a decrease in axisymmetry of the poloidal field however the percentage of toroidal field did not increase in that case.

#### 4.3.4 Results – NARVAL – 2015 March–May

Observations of  $\tau$  Boötis from March until 2015 May presented a challenge for mapping as the data were very sparse and spread over 70 d which corresponds to over 20 stellar rotations. This presents a problem due to the potential for feature evolution. In addition, only one or two observations per rotation leaves little information for determining differential rotation using the  $\chi^2$ -landscape technique.

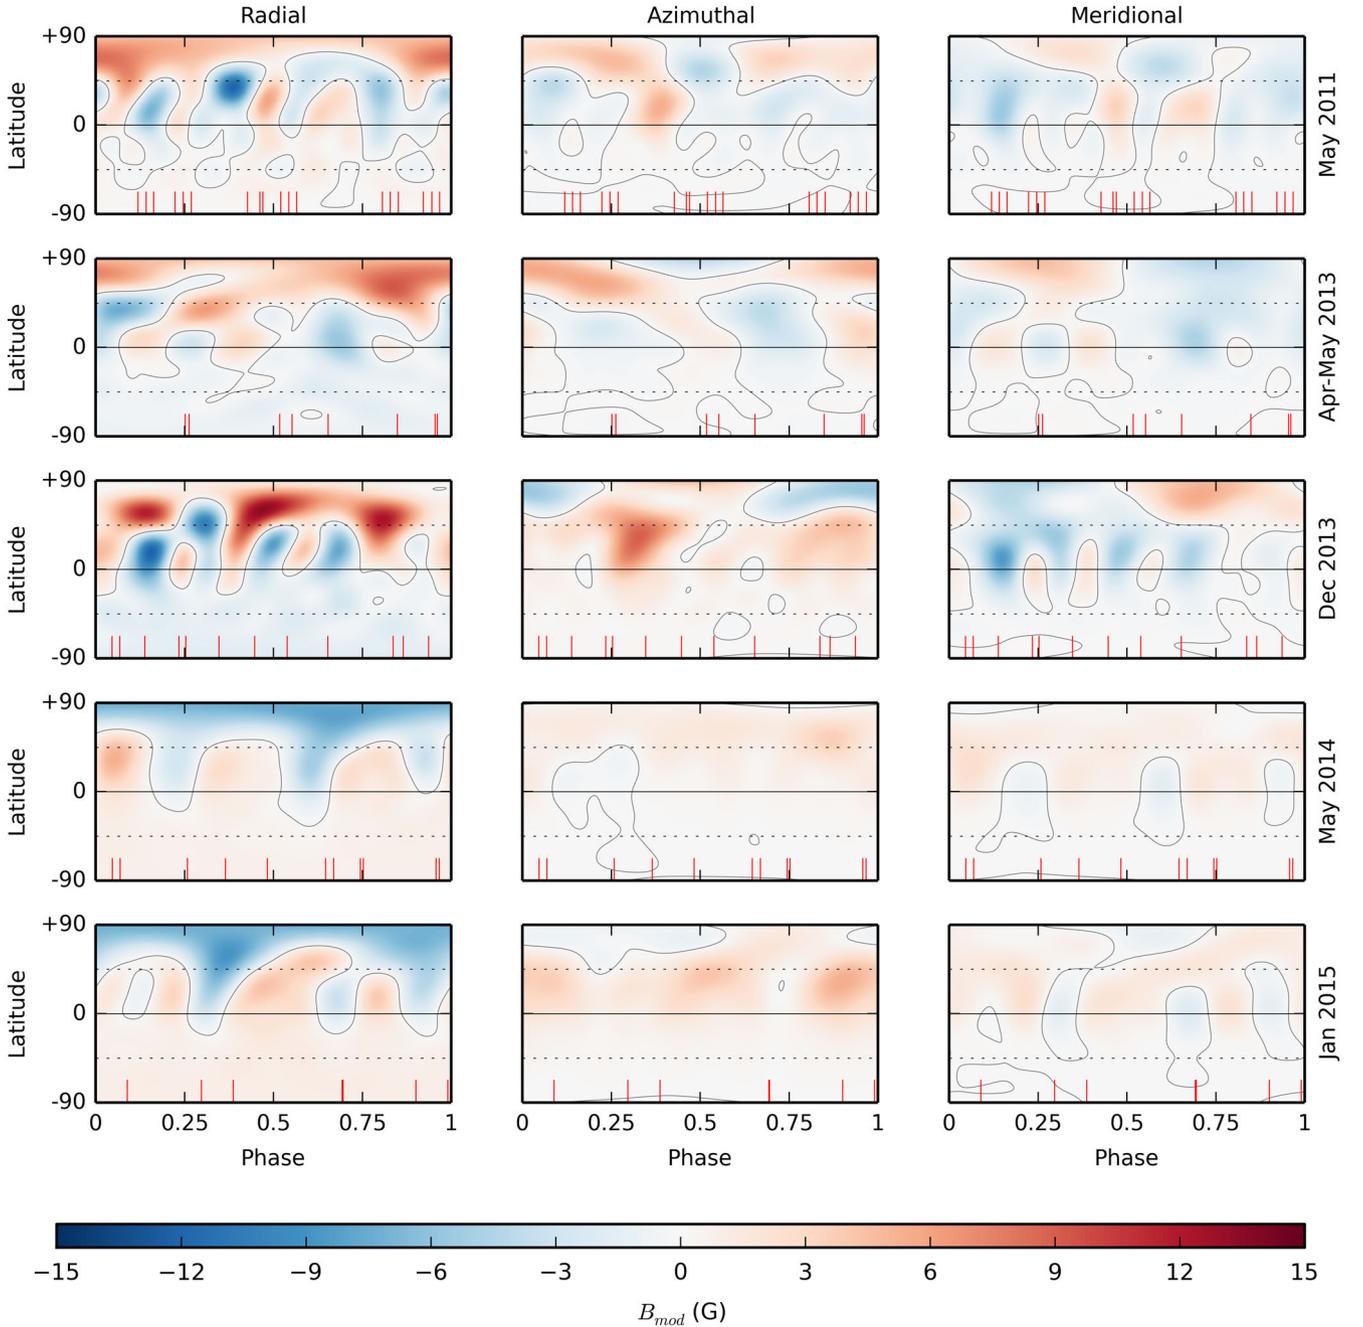

The initial three observations (2015 March 12–17) were widely separated from the rest of the data set. A crude analysis using these three observations confirmed that the expected polarity reversal had occurred, meaning that it had occurred between late January and early March. The long time base of the 2015 March–May observations presented an opportunity to investigate this activity proxy minimum using the available data.

Utilizing a sliding window of approximately eight stellar rotations, the observations from April 2 through May 27 were split into four overlapping data sets (Fig. 8, Table 4) and maps were generated. Individual differential rotation measurements were made for each of the four data sets and the measurements are summarized in Table 5. As can be seen, the  $d\Omega$  values were near solid-body and poorly defined for the first three data sets. This is probably due to insufficient data for the technique (Morgenthaler et al. 2012). For each map,  $\chi_r^2$  of 0.95 was used.

The Stokes V profiles for these data sets are shown in Fig. 9. The maps for the four data sets are shown in Fig. 10 and the resulting field configuration information is presented in Table 7. While the sparseness of the data over this period and other observational biases such as poor S/N may contribute to the lack of features, if accurate, these maps show an intriguing progression through the activity proxy minimum. The observable field strength decreases as the minimum in S-index is passed and increases dramatically as the S-index begins to rise. In all cases, the strength is less than that from the 2015 January epoch prior to the dipole reversal despite being at a higher S-index.

Fig. 8 does show that there are several observations in this epoch that suffer from comparatively poor signal to noise (circles  $S/N < 1000$ ), where no magnetic signature is detected, which has an effect on the reconstruction. In contrast, the 2015 January data (Fig. 8, data located at  $\sim$  HJD 2457030) where the measured S-indices are lower than the March–May data, apart from the final observation, the data is excellent with S/N above 1386. Apart from the lowest S-index measurement, there are detections; mostly classified as definite. Thus, it may appear at first glance that the variation in the S-index may not correlate with the level of magnetic activity we detect with ZDI due to the effects of varying data quality.

However, if we ignore the 2015 March–May observations with  $S/N < 1000$ , a pattern does appear whereas the S-index decreases, the magnetic detections become marginal until finally there is a non-detection. Further, examining all of the observations from the NARVAL epochs presented in this paper (Fig. 11, excluding

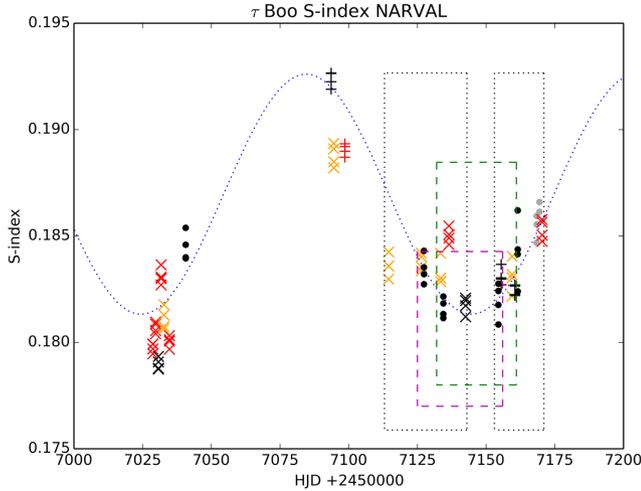

**Figure 7.** Magnetic topology of  $\tau$  Boötis reconstructed from profiles in Fig. 5 and Figs 6(a)–(d). The radial, azimuthal and meridional components of the field (with magnetic field strength labelled in G) are depicted for 2011 May (top), 2013 April and May (second row), 2013 December (third row), 2014 May (fourth row), and 2015 January (bottom row). The contour line indicates where  $B_{\text{mod}}$  is zero. The red ticks along the lower  $x$ -axes indicate the observational phases for each epoch.

$S/N < 1150$  where there is only a single marginal detection), it is clear that as the quality of the data improves, the proportion of marginal detections decreases, while non-detections only appear at lower  $S$ -indices. Hence while the data quality is a factor, it is possible to say that chromospheric activity does exhibit a relationship to the observed magnetic activity of  $\tau$  Boötis.

This may only be within a particular chromospheric activity cycle. Noting that although the  $S$ -indices for 2015 January were universally lower than 2015 March–May, the star’s magnetic field was stronger in January. This may mean that there is a general increase

in magnetic activity as the star’s magnetic cycle proceeds from one reversal to the next, while there is a smaller modulation following the chromospheric activity cycle of which there appear to be  $\sim 3$  per intra-reversal period ( $\sim 117$  d:  $\sim 1$  yr). However, the existing data are not detailed enough to make this statement definitively. Indeed, examining previous epochs and given the uncertainty in exactly when the polarity reversal occurs, it is possible to speculate that the magnetic cycle may correspond to the chromospheric cycle. Three reversals per year would potentially manifest as a yearly reversal due to observational cadences. This is discussed further in Section 5.

**Figure 8.** Ca II H&K S-indices for  $\tau$  Boötis for January ( $\sim 7030$  HJD+2450000) through 2015 May. NARVAL observations are shown as follows: red = definite detection; orange = marginal detection; black = no detection; grey = incomplete Stokes V sequence. Marker shapes represent S/N near  $\sim 700$  nm in the Stokes V spectrum: circles =  $S/N < 1000$ ;  $+$  =  $1000 < S/N < 1300$ ;  $\times$  =  $S/N > 1300$ . A least-squares fit to the unweighted data (blue line) yields a period of  $\sim 120$  d, similar to that reported in Baliunas et al. (1997). The leftmost black dotted rectangle indicates the observations used for the profiles in Fig. 9(a). The magenta and green dashed rectangles correspond to Figs 9(b) and (c), respectively. The rightmost dotted rectangle indicates the observations used for the profiles in Fig. 9(d).

**Table 4.** Use of exposures from 2015 April to May (Table B3) and their use in each map reconstruction. The rotational cycle used for calculating 0.0 (from equation 1) is shown for each map. (\* – observation on May 19 with very poor S/N was not used in the reconstruction).

**Table 5.** Summary of measured differential rotation parameters for  $\tau$  Boötis for the four maps 2015 March–May. Note the antisolar  $d\Omega$  for the first three epochs, due to poor coverage and/or low detectability of the magnetic field.

| Epoch            | $\Omega_{\text{eq}}$<br>(rad d $^{-1}$ ) | $d\Omega$<br>(rad d $^{-1}$ ) |
|------------------|--|-------------------------------|
| 2015 April 02–30 | $2.01^{+0.01}_{-0.15}$                   | $-0.07^{+0.07}_{-0.04}$       |
| 2015 May 13–12   | $1.88^{+0.15}_{-0.04}$                   | $-0.12^{+0.13}_{-0.09}$       |
| 2015 May 20–17   | $1.93^{+0.01}_{-0.01}$                   | $-0.04^{+0.04}_{-0.03}$       |
| 2015 May 12–27   | $1.92^{+0.02}_{-0.06}$                   | $+0.17^{+0.16}_{-0.14}$       |

The field configuration for 2015 March–May appears to be generally highly symmetrical for the first three data sets, however, there is very little energy in the spherical harmonics to work with during the S-index minimum. It is clear though that after the minimum, there is noticeably more toroidal field evident, and a significant decrease in poloidal axisymmetry and dipolar/quadrupolar modes. This result further suggests that a magnetic activity cycle appears to be coincident with the chromospheric activity cycle.

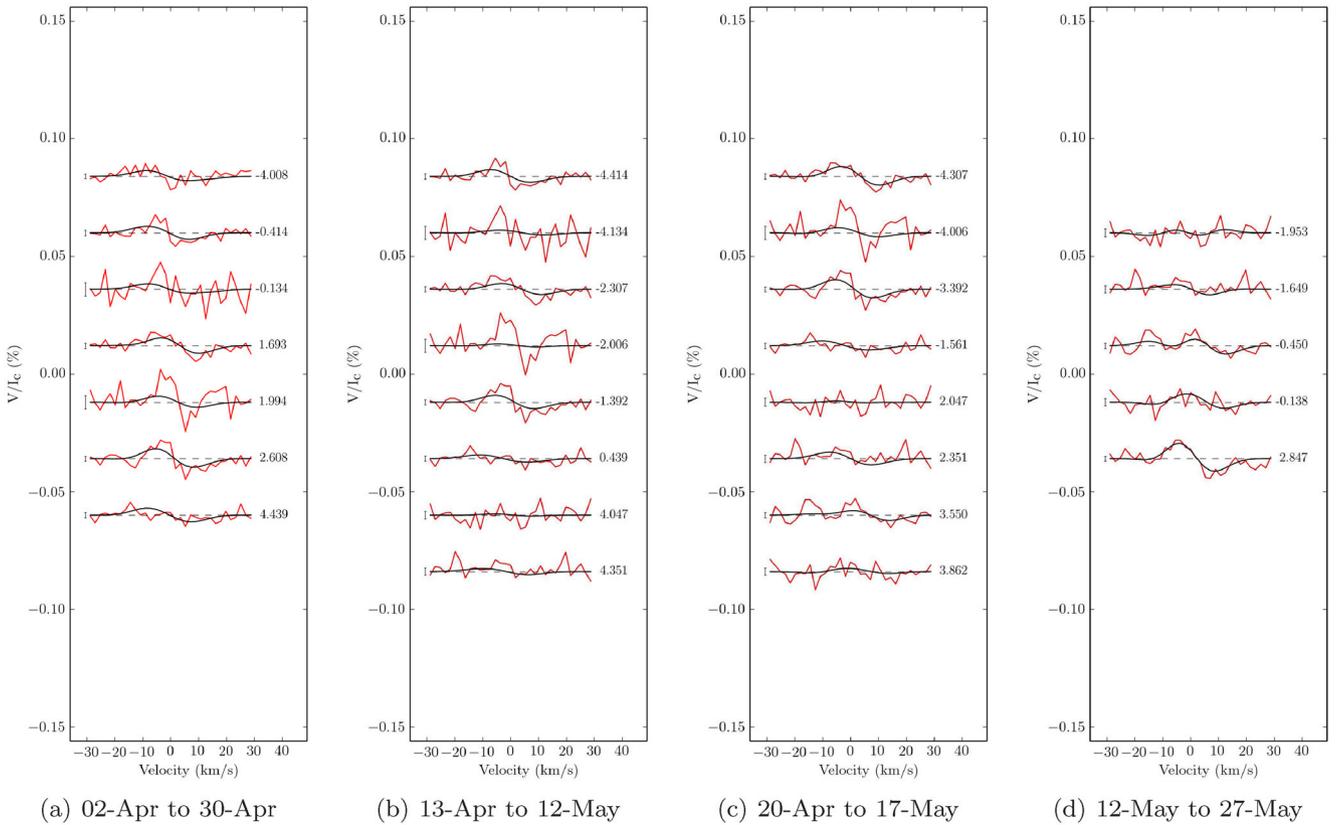

Given that  $\phi_{\text{rot}} = 0$  is synchronized in each map, it is possible to see features migrating across the star between 2015 March and May, probably due to differential rotation. In addition, in the final two data sets, the emergence of the prominent feature at  $+45^\circ$  near  $\phi_{\text{rot}} = 0.75$  with time is clear. While this may be due to observational effects, it also may be due to increased intensity leading to feature evolution. Notably, maps 1, 3 and 4, all exhibit active regions near  $\phi_{\text{rot}} = 0.75$ . Coincidentally, this is near the active longitude suggested by Shkolnik et al. (2008).

## 5 DISCUSSION AND CONCLUSIONS

The 2015 March–May observational epoch makes clear that  $\tau$  Boötis is near the limit of our ability to apply ZDI. A small magnetic survey of  $\sim 20$  planet hosting stars utilizing NARVAL (Mengel et al., in preparation) and the wider BCool survey (Marsden et al. 2014) finds that fainter stars (these surveys are to  $V \sim 9$ ) with an S-index less than  $\sim 0.2$  usually have magnetic fields too weak to detect.  $\tau$  Boötis is thus unusual in this regard, due to its brightness ( $V \approx 4.5$ ) compared to the wider sample allowing for adequate signal to noise for ZDI. When  $\tau$  Boötis is at the nadir of its chromospheric activity cycle, the magnetic field is on the very limit of where NARVAL can with confidence detect the Zeeman signature.

Despite this limitation, the evolution of the large-scale magnetic field of  $\tau$  Boötis is apparent in the results we present here over two time-scales and (what appear to be) two cyclic periods. Most significantly,  $\tau$  Boötis appears to undergo polarity switches on a regular basis. Fares et al. (2013) notes that the polarity switch appears to be a phenomenon occurring every 360 d, and these latest observations would seem to confirm this hypothesis. The regular reversals appear to occur between January and March in each calendar year. Additionally, magnetic energy appears to rise and fall in a shorter cycle coincident with the S-index of the star.

The evolution of the magnetic field during the period between reversals is illuminating insofar as the behaviour of the large-scale field broadly follows what one would expect in a star such as the Sun. In Fig. 12, the fractional magnetic field for each of the three components at each latitude is shown for these three epochs. Between 2013 April/May and December, the intensity of the radial and azimuthal components increases and the latitude at which the peak intensity is observed decreases towards the equator (Figs 12a and b). After the polarity switch, the radial and azimuthal fields have a relatively lower intensity and their peak intensity is at latitudes close to the pole (Fig. 12c). This cycle then repeats between the two observed radial field reversals (Fig. 13). This pattern of intensifying azimuthal field at lower latitudes approaching a reversal was observed between 2009 May and 2010 January, the only similar set of observations taken between a pair of reversals. It should be noted that with poorer phase coverage, the potential uncertainty in the latitudes of recovered features increases, particularly in the azimuthal and meridional components. This is because with sparser phase coverage, we are less likely to observe either the exact points of entry or exit (or indeed both) of features on the visible stellar surface. The level of this uncertainty is difficult to characterize, thus

**Figure 9.** Circular polarization profiles of  $\tau$  Boo from NARVAL 2015 April and May. As shown in Table 4, four maps utilizing a ‘sliding window’ of approximately eight rotations were used (apart from the final set of five rotations). The sets overlap and phases are as per Table 4. The observed profiles are shown in red, while synthetic profiles are shown in black. On the left of each profile, we show a  $\pm 1\sigma$  error bar. The rotational cycle of each observation is indicated on the right of each profile.

further observations with higher cadence and denser phase coverage may be required to absolutely confirm the nature of the latitudinal migration of features we propose here.

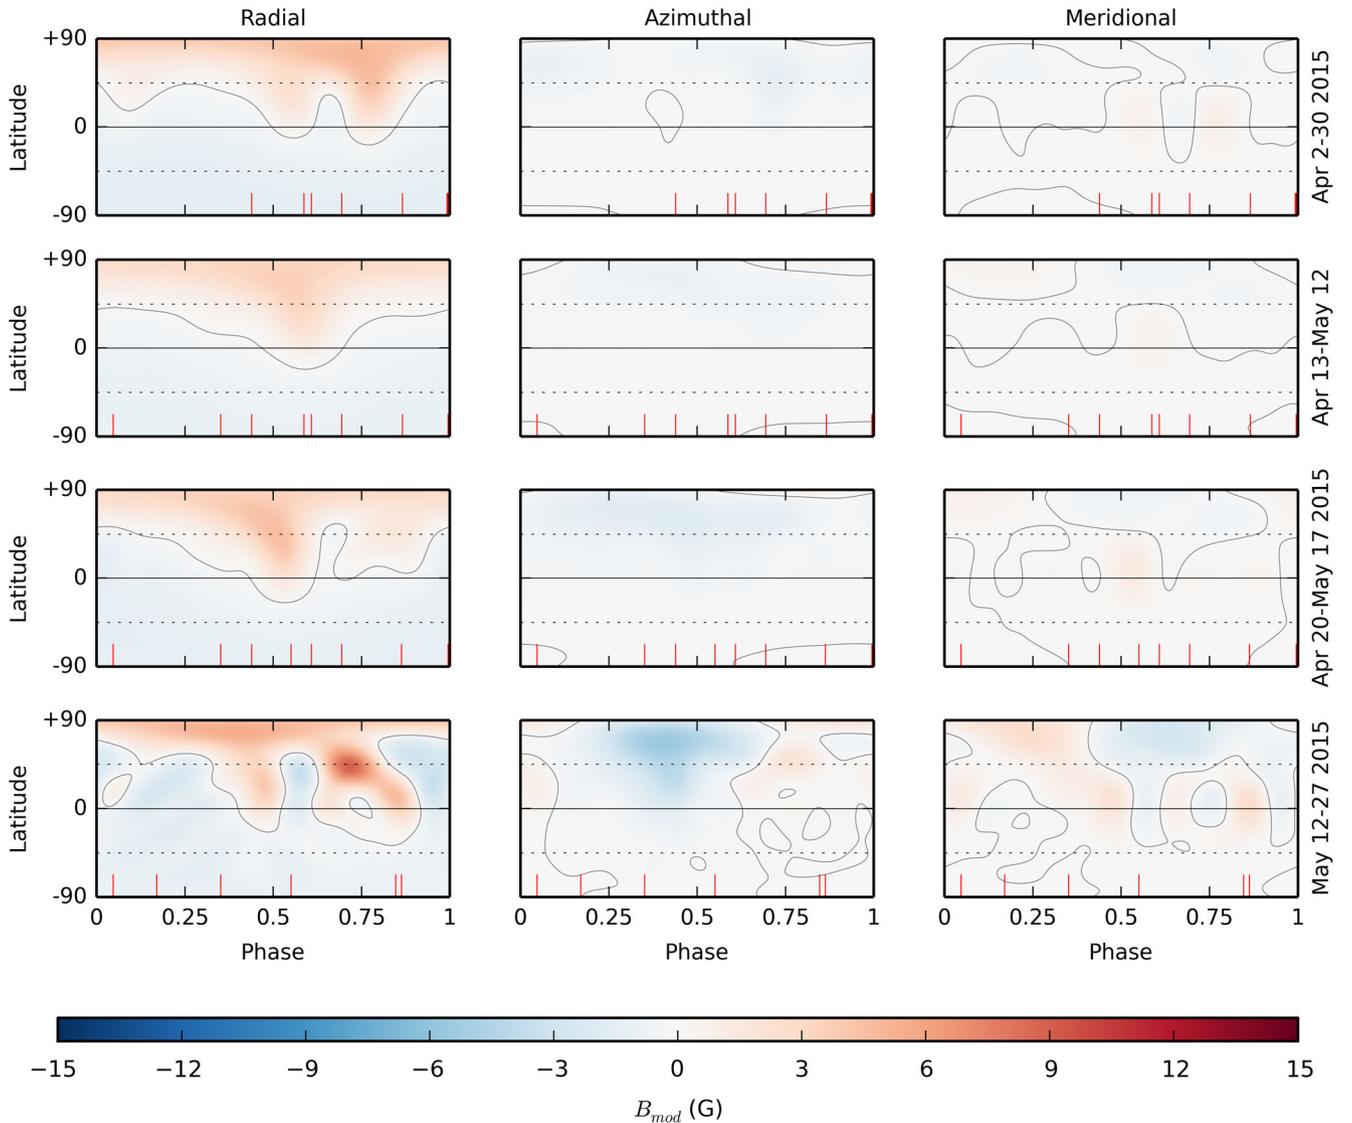

As a polarity shift approaches, the field also becomes less axisymmetric in the poloidal component and more complex, with slightly less of the poloidal field in modes corresponding to dipolar and quadrupolar components. After the polarity shift occurs, the amount of the toroidal field decreases significantly and the field becomes simpler; more axisymmetric and more strongly dipolar/quadrupolar. [Note that between 2009 May and 2010 January (Fares et al. 2013), the percentage of axisymmetric modes similarly dropped precipitously, however, the complexity of the field decreased slightly differing from the 2013 epochs].

The  $\sim 117$  d period of the  $\text{Ca II}$  H&K index coupled with a posited  $\sim$ yearly radial field polarity reversal suggests a 3:1 periodic relationship between the cycles. Reversals appear to occur at or near the peak of every third chromospheric cycle. While the sequence of maps by Fares et al. (2009), Fares et al. (2013), Donati et al. (2008) and Catala et al. (2007) indicates that the period of reversal appear to be yearly, this may not necessarily be the case. On the face of it,  $\tau$  Boötis has an approximately 720 d magnetic cycle, which is mostly, but not completely, an analogue of a solar-like cycle. Our results from 2015 March–May show that the timing of the observational epochs for  $\tau$  Boötis may in fact disguise a much faster cycle, such as the 240 d period found by Fares et al. (2013).

Fig. 14 presents the magnetic field configuration information from Tables 6 and 7, also showing the location of the approximate

date of the magnetic polarity reversal. The rapid change in the activity during 2015 March–May would seem to suggest that the magnetic activity cycle is coincident with the chromospheric activity cycle of  $\tau$  Boötis. Were reversals coincident with the peak of the chromospheric activity cycle, the similarity of the 2013–2015 January results would appear to be more related to the similarity their position in the chromospheric cycle more than any intrinsic variation between reversals. Fig. 13 also shows that the decrease in peak fractional latitude (interpreted as solar-like behaviour above) is reversed in the 2015 March–May epoch. This is perhaps due to the strengthening of the polar features in conjunction with the overall magnetic field (Fig. 15), and it would be interesting to see if the peak fractional latitude began to decrease as the chromospheric cycle continued.

Examining previous published results, no reversal between 2008 January and June would appear to settle the matter of a yearly reversal. However, given the large gap in observations between regular observations in 2008 and 2013 and the fact that three times the observational period is not exactly a year, the approximate time of the reversal may have drifted. It is possible two reversals may have occurred in the period between 2008 January and June. Further spectropolarimetric observations of  $\tau$  Boötis during each of the three  $\sim 117$  d chromospheric cycles would be required to confirm the periodicity of the polarity reversal. If the reversals are confirmed to be on a yearly basis, then a mechanism whereby the 3:1 relationship between chromospheric activity and magnetic activity would need to be posited. Magnetohydrodynamic simulations of dynamo and

**Figure 10.** Magnetic topology of  $\tau$  Boötis reconstructed from profiles in Fig. 9(a)–(d). The radial, azimuthal and meridional components of the field (with magnetic field strength labelled in G) are depicted. The contour line indicates where  $B_{\text{mod}}$  is zero. The red ticks along the lower  $x$ -axes indicate the observational phases for each epoch.

convective processes in F-type stars by Augustson, Brun & Toomre (2013) shows magnetic energy rising and falling regularly with a magnetic reversal occurring on the third such magnetic cycle, thus potentially providing such a mechanism.

Our conclusions about the behaviour of  $\tau$  Boötis should not be significantly altered were the reversal shown to be shorter. As our 2015 March–May observations show, the broad solar-like behaviour of the magnetic field of  $\tau$  Boötis should still be present, simply on a shorter time-scale.

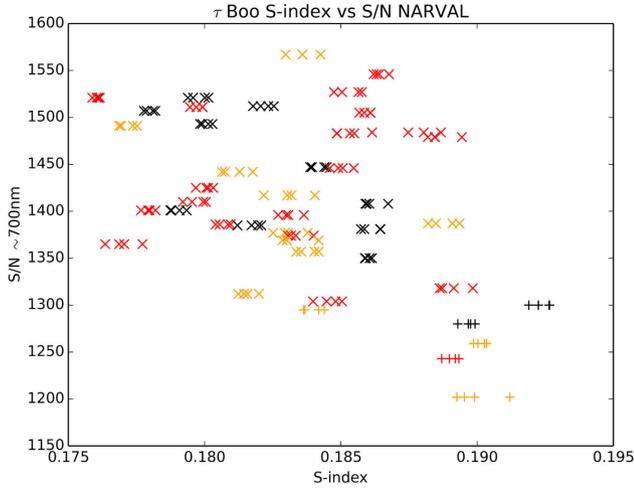

Irrespective of future work on determining the reversal cycle, an observational campaign such as 2015 March–May which spanned the maximum of the chromospheric activity would be very interesting, especially during the period of the magnetic reversal. This would provide insights into the evolution of the magnetic field leading up to, during and following a reversal.

Borsa et al. (2015) performed observations of  $\tau$  Boötis in 2013 April and May which were coincident with the 2013 April and

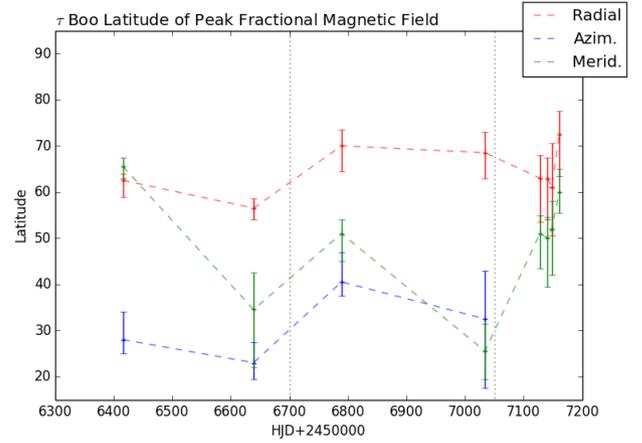

May epoch presented in this work. Unfortunately, while they observe a plage at high latitude near  $\phi_{\text{rot}} \approx 0.1$ , our observations did not provide any coverage centred on that phase. However, we do see a strong polar/high latitude magnetic feature covering  $\phi_{\text{rot}} \approx 0.85$ – $0.0$ . Given the lack of phase-coincident observations, we cannot confirm or rule out a bright spot observed by Borsa et al. (2015).

While casual observation of the maps we present in this work seem to consistently show a feature present near  $\phi_{\text{rot}} \approx 0.8$ , potentially coincident with the bright spot posited by Walker et al. (2008), analysis of all of the data does not reliably show a persistent active longitude. However, not every data set has coverage of this phase, and those that do may only have one or two observations over several rotations. Thus, we can neither rule out nor confirm if there are magnetic features potentially induced by SPI or other means.

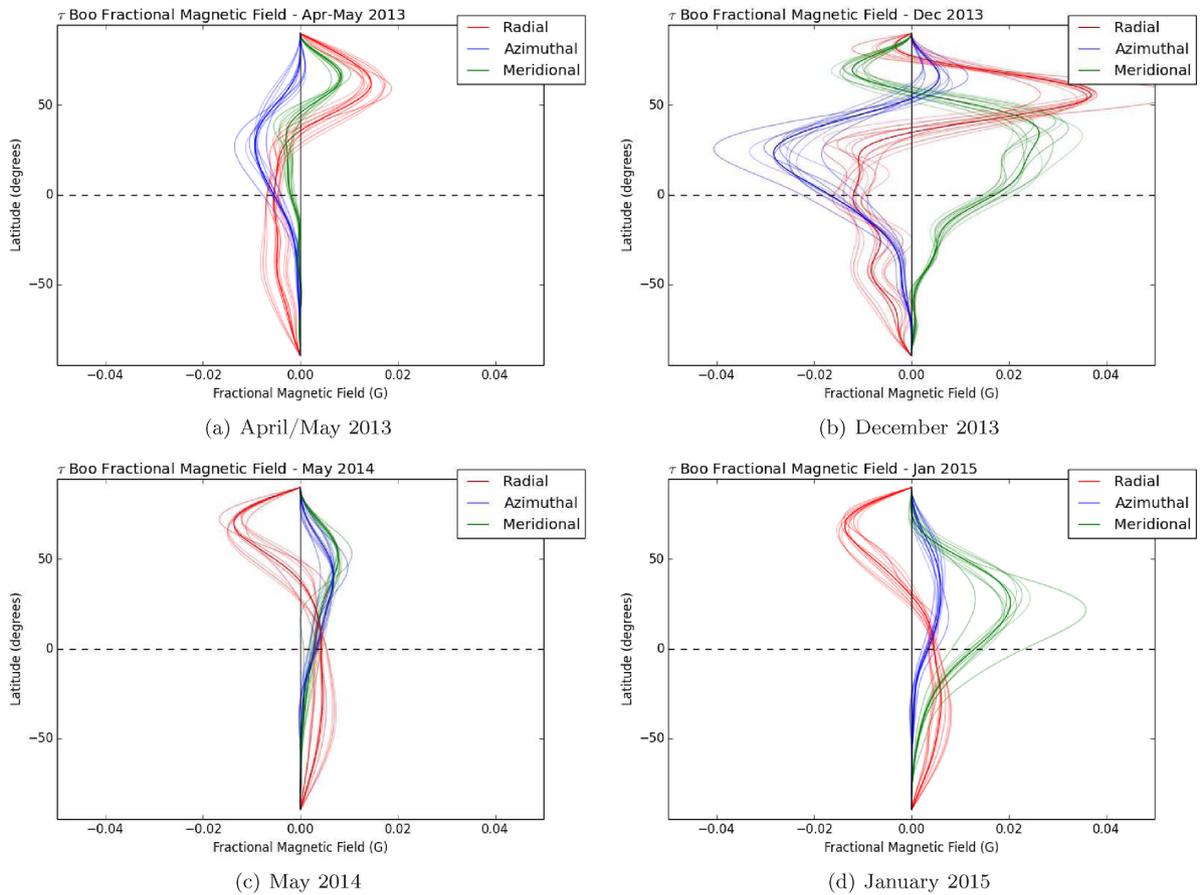

In summary,  $\tau$  Boötis is a prime candidate for further investigation. It exhibits a complex interplay of chromospheric and

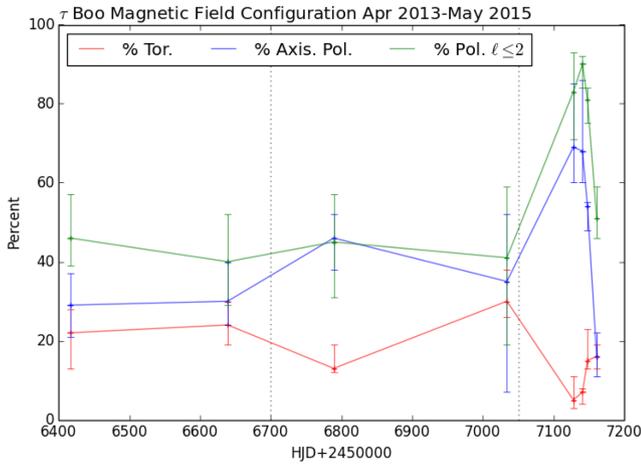

**Figure 11.** Signal to noise measured at  $\sim 700$  nm in the Stokes V spectra plotted against Ca II H&K S-indices for  $\tau$  Boötis for all NARVAL observations presented in this paper. Observations are shown as follows: red = definite detection; orange = marginal detection; black = no detection. Marker shapes represent S/N near  $\sim 700$  nm in the Stokes V profile: + =  $1000 < S/N < 1300$ ; x =  $S/N > 1300$ . There is only one marginal detection below  $SN \approx 1100$ ; all others are non-detections. These observations are excluded for clarity.

**Figure 13.** Latitude of peak fractional magnetic field components for epochs 2013 April and May–2015 January with variation bars from Fig. 12 and for the 2015 March–May epoch. The black dotted lines indicate a radial field reversal has taken place. Azimuthal field is not included for the 2015 March–May epoch for clarity as the small amount of azimuthal field is spread across a wide area, making the variation bars extremely large.

**Figure 12.** Fractional magnetic field by latitude for (a) 2013 April/May, (b) 2013 December, (c) 2014 May, and (d) 2015 January. The radial component is shown in red, azimuthal component in blue, and meridional component in green. Solid dark lines represent the result using the parameters used for mapping (inclination  $45^\circ$ ,  $v \sin i 15.9 \text{ km s}^{-1}$ ). Shaded areas represent varying inclination  $\pm 10^\circ$  and  $v \sin i \pm 1 \text{ km s}^{-1}$ . The reversal in the radial field is evident between 2013 December and 2014. The peak intensity of the field components occur at slightly lower latitudes as the reversal approaches, then revert to higher latitudes after the reversal. It is noted that the above plots assume an annual magnetic field reversal (see further discussion in Section 5).

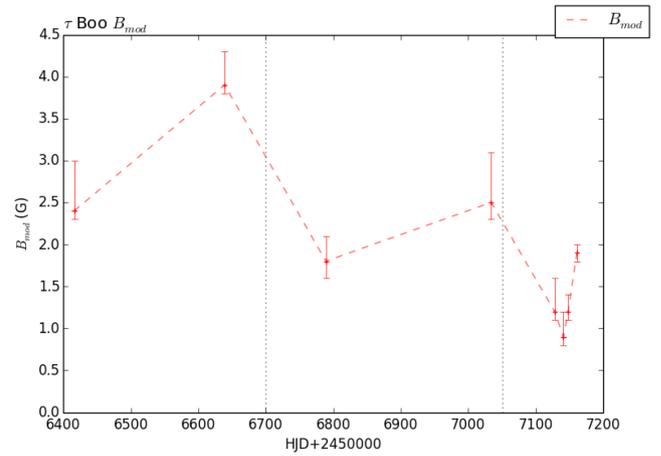

**Figure 14.** Plot of magnetic field topology from Tables 6 and 7. The black dotted lines indicate approximately where a radial field reversal has taken place. The rapid evolution of the measured field components after HJD 2457100 (2015 March–May) is coincident with the chromospheric cycle and suggests the magnetic cycle may be more rapid than the  $\sim 720$  d cycle previously assumed.

magnetic cycles. Whether the hot Jupiter orbiting the star is affecting these cycles is inconclusive, however, further observations may be able to provide more compelling information in the future.

## ACKNOWLEDGEMENTS

This work was based on observations obtained with HARPSpol (project ID 087.D-0771) at the ESO 3.6-m telescope at La Silla and with NARVAL at the TBL. TBL/NARVAL are operated by

**Figure 15.** Plot of mean magnetic field strength ( $B_{\text{mod}}$ ) from Tables 6 and 7. The black dotted lines indicate approximately where a radial field reversal has taken place.

INSU/CNRS. Previous spectropolarimetric observations of  $\tau$  Boötis were obtained from the Polarbase repository of EsPaDONs and NARVAL observations. In particular, we thank the BCool Collaboration for providing time in their long-term program for ongoing observations of  $\tau$  Boötis.

## APPENDIX A: DERIVING VARIATION MEASUREMENTS FOR MAGNETIC FIELD CONFIGURATION

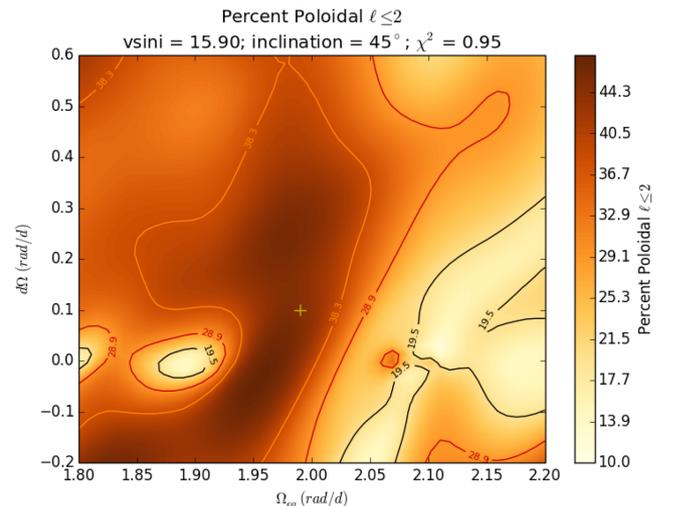

As the energy in the spherical harmonics produced by the ZDI mapping process provide exact values for a given set of modes, a measure of variability of the field configuration values (Tables 6 and 7), due to the uncertainties in the stellar parameters, is desirable. We achieve this by varying the stellar parameters, re-running the mapping process and extracting the various parameters. As variation in  $v \sin i$  and stellar inclination are used in determining the variation of the differential rotation parameters ( $\Omega_{\text{eq}}$ ,  $d\Omega$ ) (see Fig. 3b), we hold each pair of parameters ( $v \sin i$ , inclination) and ( $\Omega_{\text{eq}}$ ,  $d\Omega$ ) constant while varying the others. Otherwise, we generate extreme variations where all parameters are varied to extremes.

Fig. A1 shows a plot of the percentage of poloidal field modes  $\ell \leq 2$  from the 2014 May data set where we vary ( $\Omega_{\text{eq}}$ ,  $d\Omega$ ), holding ( $v \sin i$ , inclination) constant. Taking the  $\sim 1\sigma$  variation in ( $\Omega_{\text{eq}}$ ,  $d\Omega$ ) from the measured value (shown as a yellow cross in Fig. A1; Tables 3 and 5 show variations used) gives us an indication of how the differential rotation measurement affects this field component.

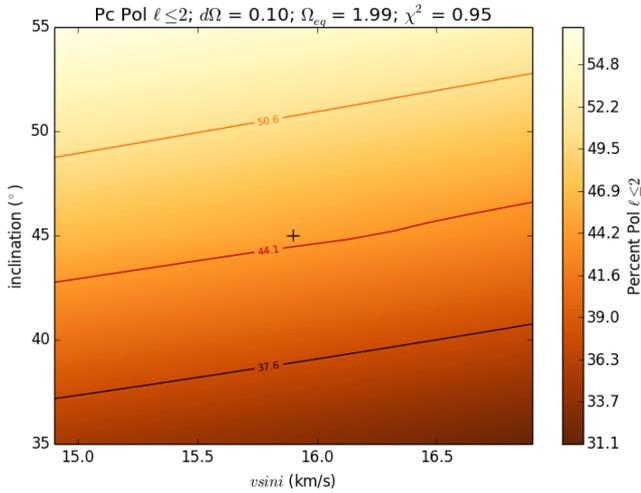

Fig. A2 similarly shows the effect on the measured field component of varying  $v \sin i$  and inclination angle while holding the DR parameters steady at the measured values.

From these measurements, we take the extreme variations from both methods to provide the variations shown in Tables 6 and 7.

It is clear that the dominant parameter for variation of poloidal axisymmetry and dipolar/quadrupolar components is the stellar inclination angle we choose. This is as expected, as errors in the assumed inclination of the star's rotational axis will affect

**Figure A1.** Plot of percentage of poloidal modes  $\ell \leq 2$  varying  $\Omega_{\text{eq}}$  and  $d\Omega$  for the 2014 May data set, using the values of  $v \sin i = 15 \text{ km s}^{-1}$  and inclination of  $45^\circ$ . The yellow cross indicates the measured differential rotation.

**Figure A2.** Plot of percentage of poloidal modes  $\ell \leq 2$  varying  $v \sin i$  and angle of inclination for the 2014 May data set, using the measured values for differential rotation. The black cross indicates the  $v \sin i$  and inclination chosen for the nominal reconstruction via  $\chi^2$  minimization described in Section 4.

axisymmetry and latitudes of features. As we use a large variation in inclination ( $\pm 10^\circ$ ), our derived variations in these values are systematically larger than those in the percentage of toroidal field and  $B_{\text{mod}}$ .

Extreme changes in  $\Omega_{\text{eq}}$  are significant, but usually, this value is relatively well constrained. Extreme variation in  $d\Omega$  can have an effect on the variation in the toroidal field component, but only if the variation is very large. If variation of  $d\Omega$  is not significantly greater than the  $\sim 1\sigma$  variation in measured value,  $d\Omega$  appears not to have a large effect on the field configuration parameters we derive.

In conclusion, we believe the field configuration parameters we derive are robust and stable, assuming the methodology we use is internally consistent using the derived parameters for  $v \sin i$ , inclination and differential rotation.

## APPENDIX B: JOURNALS OF OBSERVATIONS

**Table B1.** Journal of HARPSpol observations of  $\tau$  Boötis. Columns list the UT date, instrument used, the heliocentric Julian date (at mid-point of the series of four subexposures), the UT time (at mid-point of the series of four subexposures), the exposure time, the peak signal-to-noise ratio (SNR) of each observation (around 583 nm for HARPSpol observations), the rotational cycle from the ephemeris (from equation 1), the rotational phase (0.0 being approximately the centre of the observing run), the radial velocity (RV) associated with each exposure, and whether a magnetic signature is detected (D;  $f_{\text{ap}} < 10^{-5}$ ), marginally detected (M;  $10^{-3} > f_{\text{ap}} > 10^{-5}$ ) or is below the detection threshold (N).

**Table B3.** Journal of NARVAL observations up to and including March through 2015 May of  $\tau$  Boötis. Columns list the UT date, instrument used, the heliocentric Julian date (at mid-point of the series of four subexposures), the UT time (at mid-point of the series of four subexposures), the exposure time, the peak signal-to-noise ratio (SNR) of each observation (at around 700 nm for NARVAL), the rotational cycle from the ephemeris (from equation 1), the radial velocity (RV) associated with each exposure, and whether a magnetic signature is detected (D;  $fap < 10^{-5}$ ), marginally detected (M;  $10^{-3} > fap > 10^{-5}$ ) or is below the detection threshold (N).

| Date          | Instrument | HJD<br>(245 5000+) | UT<br>(h:m:s) | $T_{\text{exp}}$<br>(s) | SNR  | Cycle    | RV<br>(km s $^{-1}$ ) | Detection |
|---------------|------------|--------------------|---------------|-------------------------|------|----------|-----------------------|-----------|
