## ABSTRACT

**Context.** The stellar wind and the interplanetary magnetic field modify the topology of planetary magnetospheres. Consequently, the hazardous effect of the direct exposition to the stellar wind, for example, regarding the integrity of satellites orbiting the Earth or the habitability of exoplanets, depends upon the space weather conditions.

**Aims.** The aim of the study is to analyze the response of an Earth-like magnetosphere for various space weather conditions and interplanetary coronal mass ejections. The magnetopause standoff distance, the open-close field line boundary, and plasma flows toward the planet surface are calculated.

**Methods.** We used the magnetohydrodynamics code PLUTO in spherical coordinates to perform a parametric study of the dynamic pressure and temperature of the stellar wind as well as of the interplanetary magnetic field intensity and orientation. The range of the parameters we analyzed extends from regular to extreme space weather conditions, which is consistent with coronal mass ejections at the Earth orbit for the present and early periods of the solar main sequence. In addition, implications of sub-Afvénic solar wind configurations for the Earth and exoplanet magnetospheres were analyzed.

**Results.** The direct precipitation of the solar wind at the Earth dayside in equatorial latitudes is extremely unlikely even during super coronal mass ejections. On the other hand, for early evolution phases during the solar main sequence, when the solar rotation rate was at least five times faster (<440 Myr), the Earth surface was directly exposed to the solar wind during coronal mass ejections. Today, satellites at high, geosynchronous, and medium orbits are directly exposed to the solar wind during coronal mass ejections because part of the orbit at the Earth dayside is beyond the nose of the bow shock.

**Key words.** magnetohydrodynamics (MHD) – Earth – planets and satellites: magnetic fields

## 1. Introduction

Space weather forecasting in the past decades has shown the important effect of the solar wind (SW) and interplanetary magnetic field (IMF) on the state of Earth's magnetosphere, ionosphere, thermosphere, and exosphere (Poppe & Jorden 2006; González Hernández et al. 2014). Physical phenomena such as geomagnetic storms (Gonzalez et al. 1994) and substorms (Baker et al. 1999), the energization of the Van Allen radiation belts (Shah et al. 2016), ionospheric disturbances (Cherniak & Zakharenkova 2018), aurorae (Zhang & Paxton 2016), and geomagnetically induced currents at Earth's surface (Pulkkinen et al. 2017) are triggered during particular space weather conditions. Extreme space weather conditions linked to coronary mass ejections (CME) lead to a strong perturbation of the Earth's magnetosphere (Cane et al. 2000; Richardson et al. 2001; Wang et al. 2003b; Lugaz et al. 2015; Wu & Lepping 2015). The list of consequences is long: failure of spacecraft electronics due to radiation damage and charging (Choi et al. 2011), enhancement of the drag on low-orbit satellites (Nwankwo et al. 2015), spacecraft signal scintillation due to a perturbed ionosphere (Molera

Calvés et al. 2014), ground-induced electric currents that can cause the collapse of electric power grids (Cannon et al. 2013), and ionizing radiation that harms astronauts and passengers of the commercial aviation (Bazilevskaya 2005), among others. Recently, the analysis of the space weather has been generalized for the case of stars different than the Sun (Strugarek et al. 2015; Garraffo et al. 2016). Among other factors, the habitability of exoplanets depends on the space weather conditions imposed by the hosting star and the shielding efficiency of the exoplanet magnetic field, avoiding the sterilizing effect of the stellar wind on the planet surface (Gallet et al. 2017; Linsky 2019; Airapetian et al. 2020). In addition, the direct exposition of the exoplanet to the stellar wind leads to the depletion of the atmosphere, particularly, of volatile molecules such as water by thermal and nonthermal escape (Lundin et al. 2007; Moore & Khazanov 2010; Jakosky et al. 2015).

The CMEs are solar eruptions caused by magnetic reconnections in the star corona (Low 2001; Howard 2006). They expel a large amount of fast charged particles and a magnetic cloud that evolves into an interplanetary coronal mass ejection (ICME; Sheeley Jr. et al. 1985; Neugebauer & Goldstein 1997;

Cane & Richardson 2003; Gosling 1990). If the ICME impacts the Earth, the measured SW dynamic pressure increases to 10–100 nPa and the IMF intensity to 100–300 nT (Gosling et al. 1991; Huttunen et al. 2002; Manchester IV et al. 2004; Schwenn et al. 2005; Riley 2012; Howard 2014; Mays et al. 2015; Kay et al. 2017; Savani et al. 2017; Salman et al. 2018; Kilpua et al. 2019; Hapgood 2019). The Disturbance Storm Time Index ( $Dst$ ) indicates the magnetic activity derived from a network of near-equatorial geomagnetic observatories that measures the intensity of the globally symmetrical equatorial electrojet (the ring current), which is widely used to identify extreme SW and IMF space weather conditions (Sugiura & Chapman 1960; Loewe & Pröls 1997; Siscoe et al. 2006; Borovsky & Shprits, Yuri 2017). A negative  $Dst$  value means that Earth's magnetic field is weakened due to the IMF erosion, particularly during solar storms. The strongest event observed so far is the Carrington event that occurred in 1859 (Carrington 1859). An unusual large number of sunspots on the solar disk and a wide active region was registered, and an extremely fast ICME was launched from it toward the Earth. Several authors studied the Carrington event and suggested that it was a shock that traveled at about  $2000 \text{ km s}^{-1}$  (Cliver et al. 1990) that generated the strongest geomagnetic storm with  $Dst \approx -1700 \text{ nT}$  (Tsurutani et al. 2003). This was later revised to  $Dst \approx -850 \text{ nT}$  by Siscoe et al. (2006). The most recent strongest event, called the Bastille Day event (14–16 July 2000), reached a  $Dst \approx -300 \text{ nT}$  for an SW velocity of  $1000 \text{ km s}^{-1}$  and an IMF intensity of  $\approx 45 \text{ nT}$  (Rastatter et al. 2002). On the other hand, typical ICMEs impacting the Earth show an averaged plasma velocity of  $350\text{--}500 \text{ km s}^{-1}$  and IMF intensities between 9–13 nT, leading to geomagnetic storms with  $Dst < -50 \text{ nT}$  (Cane & Richardson 2003).

The interaction of the SW with planetary magnetospheres can be studied using numerical models. Different computational frameworks were used, for example, single fluid (Kabin et al. 2008; Jia et al. 2015; Strugarek et al. 2014, 2015), multi-fluid (Kidder et al. 2008), and hybrid codes (Wang et al. 2010; Müller et al. 2011, 2012; Richer et al. 2012; Turc et al. 2015). The simulations indicate a stronger compression of the bow shock as the SW dynamic pressure increases, as well as an enhancement or a weakening of the effective planet magnetic field according to the IMF orientation and intensity, leading to a modification of the magnetosphere topology (Slavin & Holzer 1979; Kabin et al. 2000; Slavin et al. 2009). Regarding the Earth magnetosphere, several magnetohydrodynamics (MHD) models were developed to analyze the interaction of the Earth magnetic field with the SW and IMF: the GEDAS model (Ogino et al. 1994), the Tanaka model (Tanaka 1994), the block-adaptive tree solar-wind Roe-type upwind scheme (BATS-R-US; Powell et al. 1999), the grand unified magnetosphere-ionosphere coupling simulation, version 4 (Janhunen et al. 2012), the Lyon-Fedder-Mobarry (LFM) model (Lyon et al. 2004), the space weather modeling framework (SWMF; Tóth et al. 2005), the open general geospace circulation model (OpenGGCM; Raeder 2003), the piecewise parabolic method with a Lagrangian remap MHD (PPMLR-MHD) model (Hu et al. 2005), and the adaptive mesh refinement conservation element and solution element AMR-CESE-MHD model (Wang et al. 2015). Thus, the effect of different SW and IMF configurations on the global structures of the Earth magnetosphere has been analyzed by several authors using MHD codes, particularly the bow shock (Samsonov et al. 2007; Andréevová et al. 2008; Nouzák et al. 2011; Mejnertsen et al. 2018), the magnetosheath (Ogino et al. 1992; Wang et al. 2004), the magnetopause standoff distance (Cairns & Lyon 1995, 1996; Wang et al. 2012), and the

magnetotail (Laitinen et al. 2005; Wang et al. 2014). In addition, global MHD models were applied to analyze the interaction of ICMEs with the Earth magnetosphere (Wu & Lepping 2002; Wu et al. 2006, 2016; Shen et al. 2011; Ngwira et al. 2013; Scolini et al. 2018; Torök et al. 2018). The simulations show large topological deformations caused by the combined effect of the SW dynamic pressure, IMF magnetic pressure, and the reconnection between the IMF and the Earth magnetic field. Consequently, the magnetopause standoff distance significantly decreases (Sibeck et al. 1991; Dušik et al. 2010; Liu et al. 2015; Nouzák et al. 2016; Grygorov et al. 2017; Samsonov et al. 2020).

Magnetohydrodynamics codes were validated by comparing the simulation results with ground-based magnetometers and spacecraft measurements (Watanabe & Sato 1990). For example, Raeder et al. (2001) compared global Earth magnetosphere simulations with magnetometer and plasma data obtained from spacecrafts during the substorm event of 24/11/1996 (dd, month, yyyy). Wang et al. (2003a) calculated the plasma depletion layer and compared the results with Wind satellite data. Den et al. (2006) developed a real-time Earth magnetosphere simulator using the data measured from the spacecraft ACE. These data were compared with geomagnetic field activities as well as with real-time plasma temperature and density data at the geostationary orbit. Facskó et al. (2016) performed a one-year global simulation of the Earth's magnetosphere comparing the results with CLUSTER spacecraft measurements. In addition, predictions of BATS-R-US, the GUMICS, the LFM, and the OpenGGCM in Honkonen et al. (2013) were compared with measurements of the Cluster (Escoubet et al. 2001), Wind (Acuña et al. 1995), and GEOTAIL (Nishida et al. 1992) missions, as well as with the Super Dual Auroral Radar Network (SuperDARN; Greenwald et al. 1995) cross polar cap potential (CPCP).

The aim of this study is to analyze the topology of the Earth magnetosphere and that of exoplanets with an Earth-like magnetosphere during CME. The novelty of our study lies in the extended use of a parametric analysis to calculate the magnetosphere deformation trends regarding the SW and IMF properties. As new results, the study encompasses a forecast of the space weather conditions that lead to the direct exposition of satellites to the SW at different orbits, as well as the direct precipitation of the SW towards the Earth/exoplanet surface. In addition, the shielding efficiency of the Earth magnetic field during the solar evolution during the main sequence until the present day is analyzed, and we identify the solar evolutionary stage that is favorable to sustain life at the Earth surface considering both standard and extreme space weather conditions, assuming a fixed intensity of the Earth magnetic field. We also analyze the ICMEs that impacted the Earth from 1997 to 2020, in particular, the response of the magnetosphere regarding the new ICME classification derived from our parametric study.

Our study was performed using the single-fluid MHD code PLUTO in spherical 3D coordinates (Mignone et al. 2007). The analysis is based on an upgraded model previously applied in the study of the global structures of the Hermean magnetosphere (Varela et al. 2015, 2016b,c,a,d) and the radio emission from exoplanets Varela et al. (2018). We performed a set of simulations with various dynamic pressure and temperature values of the SW as well as IMF intensities and orientations for the case of the Earth magnetosphere.

Single-fluid MHD simulations cannot reproduce the kinetic process on planetary magnetospheres. This leads to a deviation between simulation results and observations if the kinetic effects are strong (Chen et al. 2015; Aizawa et al. 2021).

Energy-conversion processes (Chaston et al. 2013) or ion range turbulence (Chen & Boldyrev 2017), for example, are not correctly described by MHD simulations. This is also the case for the foreshock-located upstream quasi-parallel bow shocks (Omidi & Sibeck 2007; Eastwood et al. 2008), which are linked to the formation of hot-flow anomalies (HFAs) that are created by kinetic interactions between IMF discontinuities and the quasi-parallel bow shock (Schwartz 1995; Turner et al. 2018), foreshock cavities with a low plasma density and magnetic strength, as well as enhanced wave activity (Katircioglu et al. 2009; Sibeck et al. 2021) and foreshock bubbles generated during the interactions of counter-streaming suprathermal ions with IMF discontinuities (Omidi et al. 2010; Turner et al. 2020). The foreshock causes magnetosphere disturbances that are not reproduced by single-fluid MHD models, thus kinetic (Ilie et al. 2012; Chen et al. 2017), hybrid (Lu et al. 2015; Lin et al. 2017), or multifluid (Ma et al. 2007; Manuzzo et al. 2020) models are required for an improved concurrence of simulation results and observational data. Consequently, deviations could exist between our simulation results and observational data for the case of extreme space weather configurations.

This paper is structured as follows. The simulation model, boundary, and initial conditions are described in Sect. 2. The distortion of the Earth magnetic field topology driven by the SW and IMF is analyzed in Sect. 3. The effects of the space weather conditions on the satellite integrity due to the direct exposition to the SW and the Earth habitability along the solar main sequence are discussed in Sect. 4. Finally, Sect. 5 summarizes our main conclusions, which we discuss in the context of the results of other authors.

## 2. Numerical model

The simulations were performed using the ideal MHD version of the open-source code PLUTO in spherical coordinates. The model solves the time evolution of a single-fluid polytropic plasma in the nonresistive and inviscid limit (Mignone et al. 2007). The equations solved in conservative form are

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (1)$$

$$\frac{\partial \mathbf{m}}{\partial t} + \nabla \cdot \left[ \mathbf{m} \mathbf{v} - \frac{\mathbf{B} \mathbf{B}}{\mu_0} + I \left( p + \frac{\mathbf{B}^2}{2\mu_0} \right) \right]^T = 0 \quad (2)$$

$$\frac{\partial \mathbf{B}}{\partial t} + \nabla \times (\mathbf{E}) = 0 \quad (3)$$

$$\frac{\partial E_t}{\partial t} + \nabla \cdot \left[ \left( \frac{\rho \mathbf{v}^2}{2} + \rho e + p \right) \mathbf{v} + \frac{\mathbf{E} \times \mathbf{B}}{\mu_0} \right] = 0. \quad (4)$$

$\rho$  is the mass density,  $\mathbf{m} = \rho \mathbf{v}$  is the momentum density,  $\mathbf{v}$  is the velocity,  $p$  is the gas thermal pressure,  $\mathbf{B}$  is the magnetic field,  $E_t = \rho e + m^2/2\rho + B^2/2\mu_0$  is the total energy density,  $\mathbf{E} = -(\nabla \times \mathbf{B})$  is the electric field, and  $e$  is the internal energy. The closure is provided by the equation of state  $\rho e = p/(\gamma - 1)$  (ideal gas).

The conservative forms of the equations were integrated using a Harten, Lax, Van Leer approximate Riemann solver (hll) associated with a diffusive limiter (minmod). The initial magnetic fields were divergenceless, and the condition was maintained toward the simulation by a mixed hyperbolic/parabolic divergence cleaning technique (Dedner et al. 2002).

The grid consisted of 128 radial points, 48 in the polar angle  $\theta$  and 96 in the azimuthal angle  $\phi$ . The grid was equidistant in the

radial direction, and the cell volume increased beyond the inner domain of the simulation. The simulation domain was defined as two concentric shells around the planet, with  $R_{\text{in}} = 2R_E$  the inner boundary ( $R_{\text{in}} = 3R_E$  if the SW dynamic pressure was lower than 1 nPa) and  $R_{\text{out}} = 30R_E$  the outer boundary, with  $R_E$  the Earth radius. The simulation characteristic length was  $L = 6.4 \times 10^6$  m (the Earth radius),  $V = 10^5$  m s<sup>-1</sup> the simulation characteristic velocity (order of magnitude of the SW velocity), the numerical magnetic diffusivity  $\eta \approx 5 \times 10^8$  m<sup>2</sup> s<sup>-1</sup>, and the numerical kinematic diffusivity  $\nu \approx 10^9$  m<sup>2</sup> s<sup>-1</sup>, thus the effective numerical magnetic Reynolds number due to the grid resolution is  $R_m = VL/\eta \approx 1280$  and the kinetic Reynolds number  $R_e = VL/\nu \approx 640$  (magnetic Prandtl number  $P_m = R_m/R_e = 2$ ). No explicit value of the dissipation was included in the model, hence the numerical magnetic diffusivity regulates the typical reconnection in the slow (Sweet–Parker model) regime. A detailed discussion of the numerical magnetic and kinetic diffusivity of the model is provided in Varela et al. (2018).

An upper ionosphere model was introduced between  $R_{\text{in}}$  and  $R = 2.5R_E$  where special conditions applied ( $R_{\text{in}} = 3.0$  and  $3.5R_E$  if the SW dynamic pressure was lower than 1 nPa). The upper ionosphere model is described in the Appendix A, based on the electric field generated by the field-aligned currents providing the plasma velocity at the upper ionosphere. The outer boundary was divided into the upstream part in which the stellar wind parameters were fixed and the downstream part in which the null derivative condition  $\frac{\partial}{\partial r} = 0$  for all fields was assumed. Regarding the initial conditions of the simulations, the IMF was cut off at  $R_c = 8R_E$ . In addition, a paraboloid with the vertex at the day-side of the planet was defined as  $x < A - (y^2 + z^2/B)$ , with  $(x, y, z)$  the Cartesian coordinates,  $A = R_c$  and  $B = R_c * \sqrt{R_c}$  where the velocity is null and the density profile was adjusted to keep the Alfvén velocity constant  $v_A = B/\sqrt{\mu_0 \rho} = 8 \times 10^3$  km s<sup>-1</sup> with  $\rho = nm_p$  the mass density,  $n$  the particle number, and  $m_p$  the proton mass. It should be noted that  $v_A \approx 10^4$  km s<sup>-1</sup> corresponds to a two to three times lower Alfvén velocity than the Alfvén velocity at  $R = 2.5R_E$  (Shi et al. 2013), which is required to keep the time step large enough for the simulation to remain tractable.

The Earth magnetic field was implemented as a dipole rotated 90° in the YZ plane with respect to the grid poles. In this way, the magnetic field does not correspond to the grid poles, which avoids numerical issues, thus no special treatment was included for the singularity at the magnetic poles. The effect of the tilt of the Earth rotation axis with respect to the ecliptic plane (23°) was emulated by modifying the orientation of the IMF and stellar wind velocity vectors (no dipole tilt was included for simplicity, thus the geographical and magnetic poles are the same). The simulation frame is such that the z-axis is given by the planetary magnetic axis pointing to the magnetic north pole, and the star-planet line is located in the XZ plane with  $x_{\text{star}} > 0$  (solar magnetospheric coordinates). The y-axis completes the right-handed system.

The model assumes a fully ionized proton electron plasma. The sound speed was defined as  $c = \sqrt{\gamma p/\rho}$  (with  $p$  the total electron + proton pressure and  $\gamma = 5/3$  the adiabatic index), the sonic Mach number as  $M_s = v/c$ , and the Alfvénic Mach number as  $M_a = v/v_A$ , with  $v$  the plasma velocity. Our model does not resolve the plasma depletion layer as a decoupled global structure from the magnetosheath because the model lacks the required resolution. Nevertheless, the model is able to reproduce the global magnetosphere structures as the magnetosheath and magnetopause, as was demonstrated for the case of the Hermean magnetosphere (Varela et al. 2015, 2016b,c). In addition, the reconnection between the interplanetary and Earth magnetic

field is instantaneous (no magnetic pileup on the planet dayside) and stronger (enhanced erosion of the planet magnetic field) because the magnetic diffusion of the model is stronger than the real plasma, although the effect of the reconnection region on the depletion of the magnetosheath and the injection of plasma into the inner magnetosphere is correctly reproduced in a first approximation. The Earth rotation and orbital motion are not included in the model yet either, and we leave this for future work.

Our subset of ICME simulations aims at computing the Earth magnetosphere topology for the largest forcing caused by the space weather conditions, therefore the simulation input was selected when the local maxima of dynamic pressure, IMF intensity, and southward IMF component were reached; see Appendix D for details. Nevertheless, a relaxation time is required by the Earth magnetosphere to evolve between different configurations if the space weather conditions change. The magnetosphere relaxation time due to variations in IMF orientation and intensity is linked to the reconnection rate with the Earth magnetic field, which was analyzed in detail by Borovsky et al. (2008); Burch & Phan (2016). A response time of around 6 min was measured by the Magnetospheric Multiscale Science (MMS) satellite (Fuselier et al. 2016) for the reconnection region during a northward inversion of the IMF (Trattner et al. 2016). In addition, the study by Trattner et al. (2016) indicated that slow changes in the IMF lead to a fast response time with respect to the reconnection location, although rapid changes lead to a delay of several minutes in the reconnection location response. Moreover, simulations by De Zeeuw et al. (2004) calculated an answer time of around 10 min for the subauroral ionospheric electric field after a northward IMF inversion. The relaxation time and magnetosphere dynamics due to variations in SW dynamic pressure and temperature were analyzed by Eastwood et al. (2015), Zhang & Zong (2020), Nishimura et al. (2020), Shi et al. (2020), showing a large variety of transient events that can last from seconds to one hundred minutes. Consequently, several response times exist that are linked to different magnetospheric processes, although the main response time in our study is the relaxation time required by the dayside magnetopause to reach a new equilibrium position, which is linked to the time required by the Alfvén wave to travel a distance of about the magnetopause standoff distance (Alfvén crossing time). The evolution of the space weather conditions could be very fast during the impact of the ICME, leading to inversions of the IMF components as well as local peaks of the SW dynamic pressure and temperature in a few minutes. Thus, the relaxation time could be exceeded, and the Earth magnetosphere topology would show a memory regarding previous configurations. Consequently, the simulations we performed could overestimate the forcing of the SW and IMF because the effect imprinted on the Earth magnetosphere by previous space weather conditions is not considered.

The magnetosphere response to the SW and IMF shows several interlinked phases that must be distinguished. First, the response of the dayside magnetopause and magnetosheath affecting the magnetosphere standoff distance, plasma flows toward the inner magnetosphere, or the location of the reconnection regions, among other consequences. Next, the response of the magnetotail, followed by the ionospheric response, and subsequently, the ring current response. The analysis is mainly dedicated to the dayside response of the magnetosphere. The analysis of the magnetotail is not performed in detail, although some implications regarding the magnetic field at the nightside are discussed. However, the response of the ionosphere and ring current are beyond the scope of the study.

**Table 1.** Space weather classification with respect to the SW density, velocity, and temperature as well as the IMF intensity.

Case	$n$ ( $\text{cm}^{-3}$ )	$ v $ ( $\text{km s}^{-1}$ )	$T$ ( $10^3$ K)	$ B _{\text{IMF}}$ (nT)
Normal	$\leq 10$	$< 500$	$< 60$	$\leq 10$
CME	[10, 120]	[500, 1000]	[60, 200]	[10, 100]
S-CME	$> 120$	$> 1000$	$> 100$	$> 100$

The IMF and SW parameters were fixed, that is to say, the simulation was assumed complete when steady state was reached. Thus, dynamic events caused by the evolving space weather conditions are not included in the study. The simulations reach steady state after  $\tau = L/V = 15$  code time, equivalent to  $t \approx 16$  min of physical time, although the magnetosphere topology on the Earth dayside is steady after  $t \approx 11$  min. Consequently, the code can accurately reproduce the magnetosphere response if the variation of the space weather conditions are roughly steady for time periods of  $t = 10$ – $15$  min.

The study includes the analysis of the space weather during normal, CME, and super-CME conditions. Table 1 shows the parameter range for each space weather condition.

The range of SW and IMF parameters explored in this study exceeds the present space weather condition for the Earth. The most extreme configurations show the space weather conditions that could exist during an early period of the solar main sequence or for the case of an exoplanet magnetosphere. Appendix F includes the list of SW and IMF parameters used in the different analysis performed in Sect. 3.

In addition, the effect of six different IMF orientations are considered in the study: Earth–Sun and Sun–Earth (also called radial IMF configurations), southward, northward, ecliptic clockwise, and ecliptic counterclockwise. Earth–Sun and Sun–Earth configurations indicate an IMF parallel to the SW velocity vector. Southward and northward IMF orientations show an IMF perpendicular to the SW velocity vector at the XZ plane. Consequently, because the tilt of the Earth rotation axis with respect to the ecliptic plane is included in the model, the simulations show a North–South asymmetry of the magnetosphere.

### 3. Effect of the SW and IMF on the Earth / exoplanet magnetosphere topology

Figure 1 shows a 3D view of the system for a northward IMF orientation. There is an accumulation of plasma at the planet dayside because the SW is slowed down and diverges due to the interaction with the planet magnetic field, thus the bow shock (BS) in the simulations is identified as the region showing a sudden increase in plasma density (5 times higher than the SW density). The SW dynamic pressure bends the planet magnetic field lines, which are compressed on the planet dayside and stretched at the nightside, forming the magnetotail. In addition, the planet magnetic field lines reconnect with the IMF, leading to a local erosion/enhancement of the magnetosphere. The magnetotail can extend more than  $100R_E$ , although the computation domain is limited to  $30R_E$ , thus the model only partially reproduces this magnetosphere structure if the SW dynamic pressure is  $\geq 50$  nPa and the IMF intensity is  $\leq 10$  nT. A detail discussion is provided in the Appendix C.

Figure 2 illustrates the effect of the IMF, showing the planet magnetic field, SW stream lines, reconnection region, the nose

**Fig. 1.** 3D view of a typical simulation setup. We show the density distribution (color scale), Earth magnetic field lines (red lines), and IMF (yellow lines). The yellow arrows indicate the orientation of the IMF (northward orientation). The dashed white line shows the beginning of the simulation domain (the star is not included in the model).

of the BS, and the regions in which the magnetosheath plasma is injected into the magnetosphere in the  $XY$  plane. The definition of the magnetosphere reconnection regions is given by the antiparallel reconnection model, that is to say, the regions with antiparallel magnetic fields. The simulations were performed for different IMF orientations, IMF intensities, and dynamic pressure values. In the following, the discussion of the simulation results only refers to the Earth magnetosphere for simplicity, even though some of the configurations we analyzed do not correspond to current space weather conditions. These special configurations are highlighted to avoid misunderstanding.

The simulations show a stronger compression of the magnetosphere with increasing dynamic pressure. This leads to a smaller magnetopause standoff distance; see panels a and b of Fig. 2. The simulations also show a large deformation of the Earth magnetosphere when  $|B_{\text{IMF}}|$  increases. For example, when  $|B_{\text{IMF}}|$  increases from 10 to 200 nT for a northward IMF orientation, see panels c to e, the reconnection region between the IMF and the Earth magnetic field is located closer to the poles, enhancing the plasma flows towards the Earth poles. Consequently, the IMF modifies the plasma injection into the inner magnetosphere, and therefore the plasma flows toward the Earth surface along the magnetic field lines (bold white arrows). In addition, the magnetosphere is compressed in the magnetic axis direction, and the magnetopause standoff distance decreases. Conversely, southward IMF orientations lead to a magnetic reconnection in the equatorial region that erodes the Earth magnetic field, causing a decrease in magnetopause standoff distance and the injection of SW in the inner magnetosphere at a lower latitude, see panel f. Furthermore, the Earth–Sun (Sun–Earth) IMF orientation causes a northward (southward) displacement on the dayside (DS) and a southward (northward) displacement

**Fig. 2.** Polar cut ( $XY$  plane) of the plasma density in simulations with (a) Sun–Earth IMF orientation  $|B_{\text{IMF}}| = 10$  nT  $P_d = 1.2$  nPa, (b) Sun–Earth IMF orientation  $|B_{\text{IMF}}| = 10$  nT  $P_d = 30$  nPa, (c) northward IMF orientation  $|B_{\text{IMF}}| = 10$  nT  $P_d = 1.2$  nPa, (d) northward IMF orientation  $|B_{\text{IMF}}| = 100$  nT  $P_d = 1.2$  nPa, (e) northward IMF orientation  $|B_{\text{IMF}}| = 200$  nT  $P_d = 1.2$  nPa, (f) southward IMF orientation  $|B_{\text{IMF}}| = 50$  nT  $P_d = 3$  nPa, (g) Earth–Sun IMF orientation  $|B_{\text{IMF}}| = 50$  nT  $P_d = 3$  nPa, and (h) ecliptic ctr-cw IMF orientation  $|B_{\text{IMF}}| = 50$  nT  $P_d = 3$  nPa. Earth magnetic field (red lines), SW stream functions (green lines),  $|B| = 10$  nT isocontour of the magnetic field (pink lines), and  $v_r = 0$  isocontours (white lines). The bold cyan arrows show the regions in which the plasma is injected into the inner magnetosphere.

on the nightside (NS), see panels a and g. Finally, an IMF orientation in the ecliptic plane causes an East/West tilt of the Earth magnetosphere. It should be noted that the simulations with a SW density of  $12 \text{ cm}^{-3}$  and  $|B_{\text{IMF}}| \leq 60$  nT lead to  $M_a < 1$  ( $v_A = 378 \text{ km s}^{-1}$  if  $|B_{\text{IMF}}| = 60$  nT), thus the BS is not formed. This is consistent with the observations by Lavraud & Borovsky (2008), Chane et al. (2012), Lugaz et al. (2016). This is the case of the simulations shown in panels d and e.

**Fig. 3.** 3D view of the Earth magnetosphere topology if  $|B|_{\text{IMF}} = 250$  nT for (a) a Sun–Earth, (b) southward, (c) northward, and (d) ecliptic counter-clockwise IMF orientations. We show the Earth magnetic field (red lines), SW stream functions (green lines), and isocontours of the plasma density for  $6\text{--}9\text{ cm}^{-3}$ , indicating the location of the BS (pink lines). The cyan isocontours indicate the reconnection regions ( $|B| = 60$  nT).

The deformations induced by the SW and IMF in the Earth magnetosphere during extreme space weather conditions are very strong. Figure 3 shows some examples of extreme weather conditions regarding the IMF intensity, 3D views of the Earth magnetosphere if  $|B|_{\text{IMF}} = 250$  nT, and  $P_d = 1.2$  nPa for different IMF orientations. Panel a indicates a simulation with the Sun–Earth IMF, panel b a southward IMF, panel c a northward IMF, and panel d the ecliptic counter-clockwise IMF.

The simulations show that the reconnection regions (blue isocontour of the magnetic field) and the BS (pink lines of the density isocontour cut with the XZ and XY planes) are located close to the Earth surface (slightly above  $R/R_E = 3$ ), pointing out the decrease in magnetopause standoff distance with respect to the simulation with a weaker  $|B|_{\text{IMF}}$ . The  $|B|_{\text{IMF}}$  during the impact of an ICME with the Earth is generally limited to  $|B|_{\text{IMF}} < 100$  nT, thus space weather conditions with  $|B|_{\text{IMF}} = 250$  nT fall in the category of super-ICMEs. The simulations indicate that the plasma is injected inside the inner magnetosphere through the reconnection regions, flowing along the Earth magnetic field lines from the magnetosheath toward the planet surface (green lines connected with inflow regions at  $R/R_E = 2.55$ , blue colors). If the IMF is Sun–Earth oriented, the southward bending of the magnetosphere at the Earth DS enhances the plasma flows toward the North pole. The southward IMF erodes the Earth magnetic field at the ecliptic plane, thus the plasma flows toward the Equator increase. On the other hand, the northward IMF erodes the Earth magnetic field near the magnetic axis, promoting the plasma flows toward the poles. Furthermore, the ecliptic IMF orientation induces a West/East tilt in the magnetosphere tilt, and the plasma flows toward higher longitudes.

After they reach steady state, the simulations show the formation of a low-density and high-temperature plasma belt above the upper ionosphere. The plasma belt, trapped inside the closed magnetic field lines of the Earth, is generated by two main

**Fig. 4.** (a) Polar cut (XY plane) of the plasma temperature and (b) 3D view of the Earth magnetosphere adding the plasma temperature isocontour  $T = 26$  keV (orange surface, temperature local maxima at  $R = 3R_E$  planet DS) and a polar/equatorial (XY/XZ plane) cut of the plasma density for a simulation without an IMF and  $P_d = 1.2$  nPa. The red lines indicate the Earth magnetic field lines.

sources: the SW injected into the inner magnetosphere toward the reconnection regions, and a plasma outward flux from the upper ionosphere to the simulation domain, see Fig. 4. The plasma belt in the simulations shares some features with the Van Allen radiation belt (Van Allen et al. 1958; Li & Hudson 2019) and the Earth’s ring current (Daglis 2006; Ganushkina et al. 2017), although it lacks the complexity of the real magnetosphere structures, which cannot be reproduced by a single-fluid MHD model (Hudson et al. 1997; Kress et al. 2007; Jordanova et al. 2014). In addition, the plasma belt narrows as the magnetopause standoff distance decreases, and this is not observed in simulations that reproduce extreme space weather conditions (the plasma belt is located below  $R/R_E = 2.5$ ). Likewise, other magnetosphere regions such as the plasmasphere cannot be correctly reproduced (Singh et al. 2011). Consequently, the analysis of the plasma belt, ring current, and plasmasphere are beyond the scope of our study. These model limitations can lead to deviations between the simulation results and the observational data during extreme space weather conditions.

To summarize, the correct characterization of the Earth magnetosphere topology with respect to the IMF intensity and orientation requires a detailed parametric study for regular and extreme space weather conditions. This analysis is performed in the following sections, which are dedicated to calculating the magnetopause standoff distance, the location of the reconnection regions, and the open-close field line boundary for different IMF intensities and orientations.

### 3.1. Parametric study of the magnetopause standoff distance

The magnetopause standoff distance  $R_{\text{sd}}$  can be calculated as the location where the dynamic pressure of the SW ( $P_d = m_p n_{\text{sw}} v_{\text{sw}}^2 / 2$ ), the thermal pressure of the SW ( $P_{\text{th,sw}} = m_p n_{\text{sw}} v_{\text{th,sw}}^2 / 2 = m_p n_{\text{sw}} c_{\text{sw}}^2 / \gamma$ ), and the magnetic pressure of the IMF ( $P_{\text{mag,sw}} = B_{\text{sw}}^2 / (2\mu_0)$ ) are balanced by the magnetic pressure of the Earth magnetosphere of a dipolar magnetic field ( $P_{\text{mag,E}} = \alpha \mu_0 M_E^2 / 8\pi^2 r^6$ ) and the thermal pressure of the magnetosphere ( $P_{\text{th,MSP}} = m_p n_{\text{MSP}} v_{\text{th,MSP}}^2 / 2$ ). This results in the expression

$$P_d + P_{\text{mag,sw}} + P_{\text{th,sw}} = P_{\text{mag,E}} + P_{\text{th,MSP}} \quad (5)$$

$$\frac{R_{\text{sd}}}{R_E} = \left[ \frac{\alpha \mu_0 M_E^2}{4\pi^2 \left( m_p n_{\text{sw}} v_{\text{sw}}^2 + \frac{B_{\text{sw}}^2}{\mu_0} + \frac{2m_p n_{\text{sw}} c_{\text{sw}}^2}{\gamma} - m_p n_{\text{BS}} v_{\text{th,MSP}}^2 \right)} \right]^{(1/6)}, \quad (6)$$

**Fig. 5.** Polar cut ( $XY$  plane) of the pressure balance. Simulation without IMF and  $P_d = 1.2$  nPa, isocontour of (a)  $P_d$ , (b)  $P_{\text{mag}}$  and (c)  $P_{\text{th}}$ . Simulation with northward  $|B_{\text{IMF}}| = 100$  nT and  $P_d = 1.2$  nPa, isocontour of (e)  $P_d$ , (f)  $P_{\text{mag}}$ , and (g)  $P_{\text{th}}$ . Simulation with northward  $|B_{\text{IMF}}| = 50$  nT and  $P_d = 60$  nPa, isocontour of (i)  $P_d$ , (j)  $P_{\text{mag}}$ , and (k)  $P_{\text{th}}$ . Panels d, h, and l show the total pressure ( $P_{\text{tot}} = P_d + P_{\text{mag}} + P_{\text{mag,sw}} + P_{\text{th}}$ ) normalized to the SW dynamic pressure (isocontour) as well as the isolines of  $P_d$  (white line),  $P_{\text{th}}$  (green line),  $P_{\text{mag}}$  (red line), and  $P_{\text{mag,sw}}$  (pink line), including the respective isoline values (colored characters).

with  $M_E$  the Earth dipole magnetic field moment,  $r = R_{\text{sd}}/R_E$ , and  $\alpha$  the dipole compression coefficient ( $\alpha \approx 2$ ; Gombosi 1994). This expression is an approximation, and it does not consider the effect of the reconnection of the Earth magnetic field with the IMF, that is to say, the approximation assumes a compressed dipolar magnetic field, ignoring the orientation of the IMF. Consequently, the theoretical standoff distance is only valid if  $|B_{\text{IMF}}|$  is small, thus  $R_{\text{sd}}/R_E$  should be calculated using simulations for extreme space weather conditions. In the following, the location of the magnetopause is defined as the last close magnetic field line on the Earth DS at  $0^\circ$  longitude in the ecliptic plane. Figure 5 shows the pressure balance in simulations without IMF and low  $P_d$ , large  $|B_{\text{IMF}}|$  and low  $P_d$ , as well as large  $|B_{\text{IMF}}|$  and high  $P_d$ .

The simulation without IMF and  $P_d = 1.2$  nPa shows a balance of the dynamic pressure of the SW and the combined effect of the magnetosphere magnetic and thermal pressure; see panels a to d of Fig. 5. The effect of the magnetosphere thermal pressure on the pressure balance for space weather conditions with low  $|B_{\text{IMF}}|$  and  $P_d$ , leading to  $P_{\text{th,MSP}}/P_{\text{mag,E}} \approx 1.0$  is strong. Figure 5, panels c and d, show two local maxima of  $P_{\text{th}}$  inside the BS and nearby the upper ionosphere. The  $P_{\text{th}}$  local maxima nearby the upper ionosphere are linked to the plasma belt

(see Fig. 4), whose role on the pressure balance is negligible because the magnetic pressure generated by the Earth magnetic field in this plasma region is dominant, at least one order of magnitude higher. For a northward IMF with  $|B_{\text{IMF}}| = 100$  nT and  $P_d = 1.2$  nPa, the leading terms in the pressure balance are the magnetic pressure of the IMF ( $P_d$  is 3.5 times lower) and the magnetosphere magnetic pressure (the magnetosphere thermal pressure is 4 times lower); see panels e to h. Consequently, the IMF orientation is particularly important for space weather conditions with a high IMF intensity but low SW dynamic pressure. On the other hand, the simulation for a northward IMF with  $|B_{\text{IMF}}| = 50$  nT and  $P_d = 60$  nPa indicates a balance of the magnetic pressure of the magnetosphere (the magnetosphere thermal pressure is 4–5 times lower) and the combined effect of the SW dynamic pressure and the IMF magnetic pressure; see panels i to l. In other words, the leading terms of the pressure balance during extreme space weather conditions are the dynamic pressure of the SW, the IMF magnetic pressure, and the magnetosphere magnetic pressure.

We now study the effect of the IMF intensity and orientation on the magnetopause standoff distance. For this purpose, we fixed the SW parameters to  $T_{\text{sw}} = 1.8 \times 10^5$  K and  $P_d = 1.2$  nPa. First, we must clarify that the configurations we analyzed are

**Fig. 6.** Magnetopause standoff distance with respect to  $|B|_{\text{IMF}}$  when the IMF is oriented in the Sun–Earth direction (black star), Earth–Sun (red circle), northward (blue diamond), southward (green triangle), and ecliptic ctr-clockwise direction (pink hexagon). The solid (dashed) lines indicate for each IMF orientation the data fit to the expression  $R_{\text{sd}}/R_{\text{E}} = A|B|_{\text{IMF}}^{\alpha}$  of the simulations with  $M_{\text{a}} > 1$  ( $M_{\text{a}} < 1$ ).

idealizations, that is to say, an IMF that is purely oriented in one direction is rarely observed, particularly if the IMF intensity is high. This subtlety especially applies to the radial IMF configurations because small deviations in the ecliptic component break the East–West symmetry on the model, leading to a substantial variation in the Earth magnetosphere topology. Nevertheless, all the possible configurations were analyzed for the completeness of the study, independent of the rarity of the space weather condition. Figure 6 shows the location of the magnetopause in the ecliptic plane for different IMF orientations and intensities.

Two different trends are observed in Fig. 6 for  $R_{\text{sd}}/R_{\text{E}}$  regarding the  $M_{\text{a}}$  value of the simulation. If  $M_{\text{a}} < 1$ , simulations with  $|B|_{\text{IMF}} \leq 60$  nT, the pressure balance is dominated by the magnetic pressure of the IMF and the Earth magnetic field because the BS is not formed, thus the thermal pressure of the plasma inside the BS does not participate in the balance; see Fig. 2 panels d and e as well as Fig. 5 panels d to f. On the other hand, if  $M_{\text{a}} > 1$ , the thermal pressure of the plasma inside the BS participates in the balance, particularly in the simulations with low  $|B|_{\text{IMF}}$  values; see Fig. 2 panels a and c as well as Fig. 5 panels a to d ( $P_{\text{th,MSP}}/P_{\text{mag,E}} \approx 0.4\text{--}1.0$ ). The general trend in the simulations with  $M_{\text{a}} < 1$  indicates a decrease in  $R_{\text{sd}}/R_{\text{E}}$  as the IMF intensity increases for all the IMF orientations. In contrast,  $M_{\text{a}} > 1$  simulations for the Sun–Earth and Earth–Sun IMF orientations show an increase or a constant  $R_{\text{sd}}/R_{\text{E}}$ , respectively. This exception is explained by the northward (southward) bending of the magnetosphere at the planet DS if the IMF is Earth–Sun (Sun–Earth), see Fig. 2 panel g, as well as the magnetosphere thermal pressure. The IMF orientation that leads to the lowest  $R_{\text{sd}}/R_{\text{E}}$  as  $|B|_{\text{IMF}}$  increases is the Southward orientation, while the northward IMF orientation leads to the highest  $R_{\text{sd}}/R_{\text{E}}$ . The data for each IMF orientation and  $M_{\text{a}}$  trend were fit to the expression  $R_{\text{sd}}/R_{\text{E}} = A|B|_{\text{IMF}}^{\alpha}$ , indicated by solid lines for the simulations with  $M_{\text{a}} > 1$  and by the dashed line for the  $M_{\text{a}} < 1$  simulations in Fig. 6. Table 2 shows the fitting parameters of

**Table 2.** Fit parameters of the regression  $R_{\text{sd}}/R_{\text{E}} = A|B|_{\text{IMF}}^{\alpha}$  for different IMF orientations (first column) in simulations with  $M_{\text{a}} < 1$  (second and third columns) and  $M_{\text{a}} > 1$  (fourth and fifth columns).

IMF	No BS ( $M_{\text{a}} < 1$ )		BS ( $M_{\text{a}} > 1$ )	
	A	$\alpha$	A	$\alpha$
Sun–Earth	220	−0.71	10.9	0.043
	±40	±0.04	±0.3	±0.008
Earth–Sun	210	−0.73	11.608	−0.0028
	±30	±0.03	±0.014	±0.0004
Northward	35.1	−0.345	16.5	−0.146
	±0.9	±0.005	±0.9	±0.017
Southward	33.9	−0.402	16.3	−0.209
	±1.4	±0.009	±0.7	±0.014
Ecliptic	22.2	−0.300	18.5	−0.244
	±1.3	±0.013	±0.9	±0.016

**Notes.** The standard errors of the regression parameters are included.

the regressions in the simulations with  $M_{\text{a}} < 1$  and  $M_{\text{a}} > 1$  for different IMF orientations.

The fit exponent of the simulations with  $M_{\text{a}} < 1$  for northward, southward, and ecliptic IMF orientations are close to the theoretical  $\alpha = -0.33$  value from Eq. (6), neglecting the effect of the SW thermal and dynamic pressure as well as the magnetosphere thermal pressure. The excursion from the theoretical value is a consequence of the IMF orientation, that is to say, it is due to the deviation from the dipolar magnetic field assumption. The largest deviation is observed for the southward IMF orientation because the southward IMF leads to the strongest erosion of the Earth magnetic field on the DS and the largest decrease in magnetopause standoff distance. The exponents are negative because the magnetic pressure of the IMF is opposed to that of the magnetic pressure of the Earth magnetic field. On the other hand, the fit exponents for the Earth–Sun and Sun–Earth IMF orientations are more than twice higher than the theoretical value. The large deviation is explained by the formation of two Alfvén wings at the Earth’s DS and NS (Chane et al. 2012, 2015). Figure 7, panel a, shows the Alfvén wings that formed in the simulation with Earth–Sun IMF  $|B|_{\text{IMF}} = 250$  nT and  $P_{\text{d}} = 1.2$  nPa. The Alfvén wings show the characteristic bending of the Earth magnetic field near the planet surface, the low-velocity plasma inside the wings, and a high-velocity plasma linked to the reconnection regions between the IMF and the Earth magnetic field. The IMF and Earth magnetic field magnetic pressure, see Fig. 7b, illustrates the role of the reconnection regions in the pressure balance and explains the large deviation of the fit exponents from the theoretical value. It must be pointed out that the Alfvén wings are observed during very special space weather conditions with extremely low SW densities, that is to say, the simulations performed do not represent the usual conditions for the formation of the Alfvén wings for the case of the Earth. Nevertheless, the study provides a generalization of the space weather conditions for the formation of the Alfvén wings in exoplanets with an Earth-like magnetosphere. The fit exponents of the simulations with  $M_{\text{a}} > 1$  for northward, southward, and ecliptic IMF orientations are smaller than the theoretical value because the effect of the SW dynamic pressure and magnetosphere thermal pressure cannot be neglected. If  $|B|_{\text{IMF}}$  increases, the magnetosphere thermal pressure decreases because the BS plasma is depleted faster: the reconnection regions are located closer to the Earth surface. Consequently, the pressure balance

**Fig. 7.** Polar cut (XY plane) of the (a) plasma velocity module (color scale) and (b) magnetic pressure. The red lines indicate the magnetic field lines connected to the Earth surface, and the white lines show the unreconnected IMF lines.

of the simulations with  $|B_{\text{IMF}}| \geq 20$  nT are dominated by the SW dynamic pressure and the combined effect of the magnetosphere thermal pressure and the Earth magnetic field pressure. Likewise, if  $|B_{\text{IMF}}| > 20$  nT, the combination of the SW dynamic pressure and the IMF magnetic pressure is mainly balanced by the Earth magnetic field pressure. The Earth–Sun and Sun–Earth IMF orientations show a weak dependence on  $|B_{\text{IMF}}|$ , which is a consequence of the magnetosphere bending induced by the IMF in conjunction with the thermal pressure of the magnetosphere, which is almost unchanged as  $|B_{\text{IMF}}|$  increases because the BS plasma depletion is rather weak due to the location of the reconnection region above  $12 R_E$ . This results in a magnetopause standoff distance that is nearly constant. The ecliptic clockwise and counterclockwise orientations lead to the same result.

We also considered the SW effect on the magnetosphere topology. To this end, IMF parameters were kept fixed (Sun–Earth IMF orientation with  $|B| = 10$  nT). The IMF intensity in the simulations is small, minimizing the IMF effect on the magnetosphere topology. Figure 8 shows  $R_{\text{sd}}/R_E$  for different SW densities (fixed  $T_{\text{sw}} = 1.8 \times 10^5$  K and  $|v| = 350$  km s $^{-1}$ , panel a), SW velocities (fixed  $T_{\text{sw}} = 1.8 \times 10^5$  K and  $n = 12$  cm $^{-3}$ , panel b), and corresponding dynamic pressures (panel c).

$R_{\text{sd}}/R_E$  decreases as the SW density or velocity increases, that is to say, a higher dynamic pressure leads to a stronger compression of the BS. Even if the dynamic pressure increases up to 160 nPa, extreme space weather conditions are comparable to a super-ICME,  $R_{\text{sd}}/R_E > 4.5$ . Consequently, the direct deposition of the SW toward the Earth surface requires a large distortion of the magnetosphere by the IMF in addition to the BS compression caused by the SW dynamic pressure. Again, the data were fit to the functions  $R_{\text{sd}}/R_E = An^\alpha$ ,  $R_{\text{sd}}/R_E = A|v|^\alpha$ , and  $R_{\text{sd}}/R_E = AP_d^\alpha$ . In addition, three different data sets were used in the regression, the full range of values for the SW density and velocity (dashed black line),  $P_d < 10$  nPa cases with  $n \leq 60$  cm $^{-3}$  and  $|v| \leq 600$  km s $^{-1}$  (red solid line), and  $P_d > 10$  nPa cases with  $n > 60$  cm $^{-3}$  and  $|v| > 600$  km s $^{-1}$  (solid blue line). No plateau is observed in the figures because the minimum dynamic pressure of the simulations is high enough to induce a relatively intense deformation of the magnetosphere. Table 3 shows the fitting result.

From Eq. (6), we deduce that the theoretical  $\alpha$  exponent is  $-0.17$  for the SW density and  $-0.33$  for the SW velocity, assuming a negligible effect of the IMF magnetic pressure, SW

**Fig. 8.** Magnetopause standoff distance with respect to (a) the SW density (fixed  $v = 350$  km s $^{-1}$ ), (b) SW velocities (fixed  $12$  cm $^{-3}$ ), and (c) dynamic pressure. Sun–Earth IMF orientation with  $|B| = 10$  nT. The pink stars indicate the magnetopause standoff distance if  $|B| = 0$  nT. The dashed lines indicate the data fit to the expression  $R_{\text{sd}}/R_E = An^\alpha$ ,  $R_{\text{sd}}/R_E = A|v|^\alpha$ , and  $R_{\text{sd}}/R_E = AP_d^\alpha$ . The solid red line indicates the fit line for the data set with  $n \leq 60$  cm $^{-3}$  and  $|v| \leq 600$  km s $^{-1}$ . The solid blue line indicates the fit line for the data set with  $n > 60$  cm $^{-3}$  and  $|v| > 600$  km s $^{-1}$ . The solid pink line indicates the fit line for the data set with  $n \leq 60$  cm $^{-3}$  and  $|v| \leq 600$  km s $^{-1}$  and no IMF.

thermal pressure, and magnetosphere thermal pressure in the pressure balance. The fit exponents are close to the theoretical exponents when the SW dynamic pressure is high enough ( $P_d \geq 10$  nPa) to induce a significant compression of the magnetosphere ( $R_{\text{sd}}/R_E < 7$ ), thus the pressure balance is dominated by the SW dynamic pressure and the magnetic pressure of the

**Table 3.** Fit parameters of the regressions  $R_{sd}/R_E = An^\alpha$  (first row),  $R_{sd}/R_E = A|v|^\alpha$  (second row), and  $R_{sd}/R_E = AP_d^\alpha$  (third row) for the simulations with low (second and third columns) and high (fourth and fifth columns)  $P_d$ .

SW parameter	$P_d < 10$ (nPa)		$P_d > 10$ (nPa)	
	A	$\alpha$	A	$\alpha$
Density	17.2 $\pm 0.4$	-0.219 $\pm 0.007$	12.8 $\pm 0.3$	-0.159 $\pm 0.004$
Velocity	179 $\pm 18$	-0.491 $\pm 0.019$	85 $\pm 7$	-0.386 $\pm 0.014$
Dynamic pressure	10.60 $\pm 0.06$	-0.245 $\pm 0.004$	9.0 $\pm 0.3$	-0.172 $\pm 0.011$

**Notes.** The standard errors of the regression parameters are included.

Earth magnetosphere; see the solid blue line in Fig. 8 panels a, b, and c. On the other hand, the regression exponents are 25% higher in the simulations with  $P_d < 10$  nPa; see the solid red lines in panels a, b, and c. The deviation is caused by the effect of the magnetosphere thermal pressure on the pressure balance. The ratio of the magnetosphere thermal pressure and the SW dynamic pressure increases from 0.2 to 0.5 when the SW density decreases from 60 to 6 cm<sup>-3</sup> and from 0.4 to 0.8 when the SW velocity decreases from 600 to 100 km s<sup>-1</sup>. Consequently, the magnetosphere thermal pressure must be included in the pressure balance to correctly calculate the magnetopause standoff distance when the SW dynamic pressure is low. The simulations without an IMF (pink stars) and the data fit (solid pink line) indicate the small effect of the Sun–Earth IMF with  $|B|_{\text{IMF}} = 10$  nT on the pressure balance and the Earth magnetic field topology. The regression extrapolation indicates a critical  $P_d \approx 3.5 \times 10^5$  nPa for the direct deposition of the SW toward the Earth surface, two orders of magnitude larger than the  $P_d$  values during a super-ICME for the case of the Earth. Consequently, the direct precipitation of the SW for a relatively weak  $|B|_{\text{IMF}}$  is extremely unlikely.

After the effect of the SW on the magnetopause standoff distance was assessed, we studied the effect of the plasma temperature and dynamic pressure on the thickness of the BS ( $L_{bs}/R_E$ ), with  $L_{bs}$  the distance between the BS nose and the magnetopause standoff distance at the ecliptic plane on the DS 0° longitude. An increase in SW temperature leads to an increase in sound speed and thickness of the BS. On the other hand, a higher dynamic pressure leads to a compression of the BS. Figure 9 shows the  $L_{bs}/R_E$  values that were calculated in simulations performed for a range of the SW temperatures (fixed  $P_d \approx 2$  nPa, panel a) and the  $P_d$  values (fixed  $T_{sw} = 1.8 \times 10^5$  K, panel b). In addition, the data were fit to the functions  $L_{bs}/R_E = AT_{sw}^\alpha$  and  $L_{bs}/R_E = AP_d^\alpha$ .

The simulations indicate an increase in BS width of  $\approx 0.4 R_E$  when the SW temperature increases from  $5 \times 10^4$  to  $2 \times 10^5$  K (panel a). On the other hand, the BS width decreases  $\approx 2.8 R_E$  when  $P_d$  raises from 0.2 to 160 nPa (panel b). That is to say, the BS compression caused by the SW  $P_d$  is around 6–7 times higher than the BS expansion due to the SW temperature. Moreover, the BS compression is lower in the simulations with fixed SW velocity because the plasma temperature and sound speed inside the BS are higher as well as  $P_{th}$ . In addition, the simulations with  $P_d < 4$  nPa show a weaker dependence of the BS width on  $P_d$  (compare the regression parameters of the simulations with

**Fig. 9.** BS width for (a) different SW temperatures (fixed  $P_d = 1.2$  nPa) and (b) different  $P_d$  values (fixed  $T_{sw} = 1.8 \times 10^5$  K) when the SW density increases (fixed the SW velocity to 350 km s<sup>-1</sup>, red dots) or the SW velocities increases (fixed the SW density to 12 cm<sup>-3</sup>, blue dots). Sun–Earth IMF orientation with  $|B| = 10$  nT. The dashed lines indicate the data fit to the expression  $L_{bs}/R_E = AT_{sw}^\alpha$ . The solid black lines indicate the regression  $L_{bs}/R_E = AP(n_{SW})_d^\alpha$  in the simulations with the SW velocity fixed and  $P_d > 4$  nPa and  $L_{bs}/R_E = AP(v_{SW})_d^\alpha$  in the simulations with the SW density fixed and  $P_d < 4$  nPa. The solid violet (orange) line indicates the regression  $L_{bs}/R_E = AP(n_{SW})_d^\alpha$  ( $L_{bs}/R_E = AP(v_{SW})_d^\alpha$ ) when  $P_d < 4$  nPa.

$P_d > 4$  nPa and  $P_d < 4$  nPa) because the magnetosphere thermal pressure is comparable to  $P_d$ . By contrast, as the simulation  $P_d$  increases and the role of the magnetosphere thermal pressure is less important in the pressure balance, the dependence of the BS width on  $P_d$  increases. The range of SW temperature and  $P_d$  values we highlighted includes the typical SW parameters during regular and extreme space weather conditions (Cliver et al. 1990; Mays et al. 2015).

In summary, the magnetopause standoff distance we calculated in the simulations reveals the key role of the IMF and SW in the distortion of the Earth magnetosphere for regular and extreme space weather conditions. The data regressions show clear differences in the pressure balance for super-Alfvénic and sub-Alfvénic configurations, as well as the important role of the magnetosphere thermal pressure in the determination of the magnetopause standoff distance when the SW dynamic pressure

**Fig. 10.** Location of the reconnection regions in the  $XY$  plane when  $|B_{\text{IMF}}|$  increases from 10 to 250 nT for Earth–Sun and Sun–Earth IMF orientations.  $P_d = 1.2$  nPa and  $T_{\text{sw}} = 1.8 \times 10^5$  K. The color of the symbols indicates the  $|B_{\text{IMF}}|$  value. The stars indicate the reconnection region for the Sun–Earth IMF orientation. The circles indicate the reconnection region for the Earth–Sun IMF orientation.

and IMF magnetic pressure are low. The range of magnetopause standoff distance we calculated is comparable to the results obtained by other authors (Song et al. 1999; Kabin et al. 2004; Lavraud & Borovsky 2008; Ridley et al. 2010; Meng et al. 2012; Wang et al. 2015). The contribution of our study entails a larger sample of space weather configurations through the extended parametric studies we performed, as well as through the detailed analysis of the topological deformation trends that are linked to the SW and IMF properties.

### 3.2. Reconnection region tracking for different IMF orientations and intensities

This section is dedicated to tracking the location of the reconnection regions for different IMF orientation and intensities. Figure 10 indicates the location of the reconnection regions in the  $XY$  plane for Sun–Earth and Earth–Sun IMF orientations as  $|B_{\text{IMF}}|$  increases from 10 to 250 nT. Likewise, Fig. 11 shows the same study for northward and southward IMF orientations. The reconnection in the simulations is identified as the region in which the magnetic field intensity goes to zero.

The reconnection region for the Sun–Earth IMF orientation on the DS moves toward the South pole as  $|B_{\text{IMF}}|$  increases, showing a large northward displacement, but this is smaller in the Earth-ward direction. On the other hand, the reconnection on the NS moves toward the North pole, and the larger displacement is found in the sunward direction with respect to the southward displacement. Regarding the Earth–Sun IMF orientation, the reconnection on the DS moves southward toward the North pole, although the reconnection on the NS moves toward the South pole. The differences between the Sun–Earth and Earth–Sun orientations are caused by the North-South bending of the Earth magnetosphere. The reconnection region on the NS is located outside the computational domain for the simulations with  $|B_{\text{IMF}}| < 30$  nT, thus these data were not included in the analysis.

The reconnection region in the simulations with a southward IMF orientation are located closer to the equatorial plane and the

**Fig. 11.** Location of the reconnection regions in the  $XY$  plane when  $|B_{\text{IMF}}|$  increases from 10 to 250 nT for northward and southward IMF orientations.  $P_d = 1.2$  nPa and  $T_{\text{sw}} = 1.8 \times 10^5$  K. The color contour indicates the  $|B_{\text{IMF}}|$  value. The yellow (gray) star indicates the reconnection region on the DS (NS) for a southward IMF orientation. The yellow (gray) circle indicates the reconnection region near the North (South) pole for the northward IMF orientation.

Earth surface as  $|B_{\text{IMF}}|$  increases. On the DS, the reconnection displaces southward and earthward. Regarding the northward IMF orientation, the reconnections are located closer to the poles as  $|B_{\text{IMF}}|$  increases. The reconnection region on the NS is outside the computational domain for the simulations with southward IMF and  $|B_{\text{IMF}}| < 60$  nT, and also for the simulations with northward IMF and  $|B_{\text{IMF}}| < 40$  nT. These regions were not considered.

Figure 12 shows the location of the reconnection region for an ecliptic ctr-clockwise IMF orientation as  $|B_{\text{IMF}}|$  increases. The clockwise case is not included because the Earth magnetosphere shows a symmetric topology deformation with respect to the ecliptic IMF orientations. The analysis is more complex regarding the other IMF orientations because the reconnections are not located in the  $XY$  plane and should be tracked in 3D.

The reconnection regions move toward the planet surface as the  $|B_{\text{IMF}}|$  increases, following the East/West tilt induced in the Earth magnetosphere. The reconnection region is outside the computational domain for the simulations with  $|B_{\text{IMF}}| < 20$  nT.

To summarize, the location of the reconnection regions is critical for understanding the effect of the IMF orientation and intensity on the topology of the Earth magnetosphere. The study reveals a large variation in this topology in the range of IMF intensities and orientations we analyzed. Consequently, the SW injection into the inner magnetosphere and the plasma flows toward the Earth surface are very different regarding the IMF configuration. Table 4 shows the percentage of the reconnection displacement for different IMF orientations (defined as  $100 \cdot \Delta r_{\text{max}} / \Delta r_{\text{min}}$  with  $\Delta r = \sqrt{\Delta x^2 + \Delta y^2 + \Delta z^2}$ ) between the simulations with  $|B_{\text{IMF}}| = 250$  nT and  $|B_{\text{IMF}}|_{\text{min}}$  (third and fifth columns). The third and fifth columns also indicate whether the reconnection regions are located on the DS, NS, at the North pole, South pole, and West or East of the magnetosphere. If the reconnection region is located outside the computational domain (because  $|B_{\text{IMF}}|$  is small), the simulation is not included in the analysis and the configuration with the lowest  $|B_{\text{IMF}}|$

**Fig. 12.** Location of the reconnection region if  $|B_{\text{IMF}}|$  increases from 10 to 250 nT for an ecliptic ctr-clockwise IMF orientation.  $P_d = 1.2$  nPa and  $T = 1.8 \times 10^5$  K. The color contour indicates the  $|B_{\text{IMF}}|$  value. *Panel a* indicates the projection in the YZ plane, *(b)* the projection in the XZ plane, and *(c)* the projection in the XY plane. *Panel d* shows the 3D view.

**Table 4.** IMF orientation (first column).

IMF	$ B_{\text{IMF}} _{\text{min}}$ (nT)	DS (%)	$ B_{\text{IMF}} _{\text{min}}$ (nT)	NS (%)
Sun–Earth	10	46.37	30	17.02
Earth–Sun	10	35.58	30	16.97
Southward	10	34.42	60	20.93
Northward	40	North P. 19.39	40	South P. 18.94
Ctr-cw Ecliptic	20	West 18.54	20	East 19.30

**Notes.** IMF intensity of the simulation with the lowest  $|B_{\text{IMF}}|$  and the reconnection region located inside the computational domain (second and fourth columns). Maximum reconnection displacement in percent between the simulations with maximum and minimum  $|B_{\text{IMF}}|$  on the DS (NS) for Sun–Earth, Earth–Sun, and southward IMF orientations, for the North (South) pole for the northward orientation, and for West (East) of the magnetosphere for the ctr-cw ecliptic IMF orientation (third and fifth columns, respectively).

with the reconnection region inside the computational domain is indicated in the table (second and fourth columns).

### 3.3. Open and closed field line boundary for different IMF orientations and intensities

The modification of the topology of the Earth magnetosphere by the IMF also modifies the ratio between open and closed magnetic field lines at the Earth surface. The Earth surface covered by open field lines is more vulnerable to extreme SW conditions because the plasma precipitates along the magnetic field

lines toward the surface. If a large amount of SW is injected into the inner magnetosphere through the reconnection regions, the plasma flows on the planet surface, which is covered by open field lines, are higher. Consequently, it is important to study the modification that the IMF intensity and orientation cause on the latitude of the open and closed field line boundary (OCB). Figure 13 shows the open magnetic field lines at  $R/R_E = 2.05$  for different IMF intensities and orientations (fixed  $P_d = 1.2$  nPa and  $T_{\text{sw}} = 1.8 \times 10^5$  K). The OCB lines are identified by an iterative method that calculates the last close magnetic field line connecting the inner boundary of the computational domain and concentric spheres with radius between  $R_{\text{sd}}/R_E$  and  $(R_{\text{sd}} + R_E)/R_E$ . The magnetotail is fully located inside the simulation domain in the configurations we analyzed; see the Appendix C for further discussion.

The increase in  $|B_{\text{IMF}}|$  for a Sun–Earth IMF orientation (panel a) causes a decrease in OCB latitude on the DS, which is particularly large in the North Hemisphere. This result is consistent with the southward bending of the Earth magnetosphere, promoting a stronger erosion of the Earth magnetic field by the IMF in the North Hemisphere. The east-west tilt of the magnetosphere caused by the IMF orientations in the ecliptic plane (panel b) is also observed in the open field line distribution, leading to a large longitudinal and latitudinal OCB dependence. Regarding the Sun–Earth and Earth–Sun IMF orientations (panels c and d), the OCB is asymmetric with respect to the DS and NS. On the other hand, the displacement of the reconnection regions toward the Earth magnetic axis (equatorial plane) for a northward (southward) IMF orientation leads to a displacement of the OCB towards a higher (lower) latitude (panels e and f). The southward IMF orientation leads to the lowest OCB latitude on the DS and NS for both hemispheres.

The latitude of the OCB at the Earth surface was calculated by mapping the magnetic field lines obtained in the simulations

**Fig. 13.** Sinusoidal (Sanson-Flamsteed) projection of the open and closed magnetic field line boundary at  $R/R_E = 2.05$  for (a)  $|B_{\text{IMF}}| = 0$  nT, (b) ecliptic ctr-clockwise  $|B_{\text{IMF}}| = 250$  nT, (c) Sun–Earth  $|B_{\text{IMF}}| = 250$  nT, (d) Earth–Sun  $|B_{\text{IMF}}| = 250$  nT, (e) northward  $|B_{\text{IMF}}| = 250$  nT, and (f) southward  $|B_{\text{IMF}}| = 250$  nT. Fixed  $P_d = 1.2$  nPa and  $T_{\text{sw}} = 1.8 \times 10^5$  K. The yellow (orange) dots indicate the open magnetic field lines at the Earth DS (NS).

**Fig. 14.** OCB latitude with respect to the IMF orientation and  $|B_{\text{IMF}}|$  calculated in the North Hemisphere (a) DS ( $0^\circ$  longitude) and (b) NS ( $180^\circ$  longitude), South Hemisphere (c) DS and (d) NS. Fixed  $P_d = 1.2$  nPa and  $T_{\text{sw}} = 1.8 \times 10^5$  K. The dashed horizontal lines indicate the  $K_p$  index. The yellow star indicates the OCB latitude if  $|B_{\text{IMF}}| = 0$ . IMF direction: Sun–Earth (black star), Earth–Sun (red circle), northward (blue diamond), southward (green triangle), and ecliptic ctr-clockwise (cyan pentagon).

with the magnetic field of a dipole without the distortion of the SW and IMF. The magnetic field line mapping is described in the Appendix B, where we show that below  $2R_E$ , the unperturbed and perturbed dipoles agree well, thus the OCB line latitude at the Earth surface can be extrapolated with reasonable confidence. Figure 14 indicates the OCB latitude with respect to

the IMF orientation and  $|B_{\text{IMF}}|$  calculated on the Earth DS ( $0^\circ$  longitude) and NS ( $180^\circ$  longitude) in the North and South Hemispheres. In addition, the OCB latitude is compared with the latitude of the auroral oval associated with different  $K_p$  indices. The  $K_p$  index indicates the global geomagnetic activity. It takes values from 0 for the case of weak geomagnetic activity to 9 if there is extreme geomagnetic activity (Menvielle & Berthelier 1991; Thomsen 2004).

The OCB latitude on the North Hemisphere DS (panel a) decreases from  $70^\circ$  to  $58^\circ$  as  $|B_{\text{IMF}}|$  increases for the Sun–Earth IMF orientation. Regarding the Earth–Sun IMF orientation, the range of OCB latitudes is slightly smaller, between  $68 - 58^\circ$ , due to the northward bending of the magnetosphere on the DS, leading to slight differences with respect to the Sun–Earth IMF in the North Hemisphere, but causing larger differences in the South Hemisphere (panel c). On the other hand, the northward IMF orientation leads to an increase in OCB latitude in the North Hemisphere up to  $80^\circ$  if  $|B_{\text{IMF}}| = 100$  nT, which decreases to  $76^\circ$  if  $|B_{\text{IMF}}| = 250$  nT due to the combined effect of the magnetosphere compression and the tilt. On the other hand, the OCB latitude in the South Hemisphere increases when  $|B_{\text{IMF}}|$  reaches  $88^\circ$  for  $|B_{\text{IMF}}| = 250$  nT simulation. The trend of the OCB latitude regarding  $|B_{\text{IMF}}|$  is inverted between hemispheres on the planet NS (see Fig. 10), again due to the effect of the magnetic field tilt. For the southward IMF orientation, the OCB latitude decreases as  $|B_{\text{IMF}}|$  increases, between  $63 - 53^\circ$  in the North Hemisphere and  $63 - 51^\circ$  in the South Hemisphere if the simulations with  $|B_{\text{IMF}}| = 10$  and  $250$  nT are compared due to the Earth magnetic field erosion at the equatorial region. For the ecliptic ctr-clockwise orientation, the OCB latitude slightly decreases as  $|B_{\text{IMF}}|$  increases, from  $65^\circ$  to  $61^\circ$  when  $|B_{\text{IMF}}|$  increases from 10 to 250 nT, because the west-east asymmetry induced in the magnetosphere has a lesser effect on the OCB latitude. The latitude of the auroral oval for different  $K_p$  index is included in the panels and compared with the OCB latitude at the Earth DS and NS, providing an approximation of the  $K_p$  index in the simulations. The largest variation in OCB line with respect to the  $K_p$  index as  $|B_{\text{IMF}}|$  enhances is observed for the Earth–Sun and southward IMF orientations. Consequently, Earth–Sun and southward IMF orientations can lead to strong geomagnetic activities. This result is consistent with previous studies by Schatten & Wilcox (1967); Boroyev et al. (2020). The Sun–Earth, northward, and ecliptic IMF orientations lead to  $K_p \leq 4$  if  $|B_{\text{IMF}}| = 250$  nT, thus the geomagnetic activity that is caused is relatively quiet. The latitudinal resolution of the model is  $4^\circ$ , thus the uncertainty on the  $K_p$  index prediction is  $\pm 2$ , which is enough to distinguish between quiet ( $K_p < 3$ ), moderate ( $3 \leq K_p \leq 6$ ), and strong ( $K_p > 6$ ) auroral activity.

In summary, the OCB latitude, and so the exposition of the Earth surface to the plasma flows from the magnetosheath, shows a clear dependence on the space weather conditions, leading to a large decrease in OCB latitude, in particular for an intense southward oriented IMF. For example, Fig. 15 shows the OCB line for different IMF orientations with  $|B_{\text{IMF}}| = 250$  nT, indicating that the South of Canada and the North of England are exposed if the IMF orientation is southward, thus the electric grids of these countries are in danger. Similar trends were obtained by other authors with respect to the IMF orientation and intensity (Lopez et al. 1999; Kabin et al. 2004; Wild et al. 2004; Wang et al. 2016; Burrell et al. 2020). We extended and refined these results here through the large sample of parametric studies we performed, including a forecast of the  $K_p$  index variation with respect to the IMF module and orientation.

**Fig. 15.** Schematic view of the OCB line for Sun–Earth (black line), Earth–Sun (red line), northward (blue line), southward (green line), and ecliptic ctr-clockwise (cyan lines) with  $|B_{\text{IMF}}| = 250$  nT. The parameters  $P_d = 1.2$  nT and  $T_{\text{sw}} = 1.8 \times 10^5$  K are fixed. The location of the DS and NS with respect to the continents is irrelevant.

**Fig. 16.** Isocontour of the magnetopause standoff distance for different  $P_d$  and  $|B_{\text{IMF}}|$  values when the IMF is oriented (a) Earth Sun, (b) ecliptic ctr-clockwise, (c) southward, and (d) northward. The parameter  $T = 1.8 \times 10^5$  K is fixed.

### 3.4. Combined effect of the dynamic pressure and IMF orientation and intensity on the topology of the Earth magnetic field

A complete parametric study of the topology of the Earth magnetosphere with respect to space weather conditions requires the combined effect of the SW dynamic pressure and the IMF module and orientation. With this aim, Fig. 16 indicates the magnetosphere standoff distance with respect to the IMF orientation and module (for  $|B_{\text{IMF}}| = 50, 100, 150, 200$  and  $250$  nT) and the SW dynamic pressure ( $P_d = 1.2, 1.5, 3, 4.5, 6, 15, 30, 45, 60, 80,$  and  $100$  nPa). The range of parameters includes regular and extreme space weather conditions (ICME). Ecliptic clockwise and counterclockwise IMF orientations lead to the same results. We therefore only analyzed the counterclockwise case. The Sun–Earth orientation is not included because in spite of the magnetic field tilt, there is a North–South symmetry with respect of the Earth–Sun orientation so that the simulations results are similar.

The IMF orientation that leads to the smallest magnetopause standoff distance with respect to  $|B_{\text{IMF}}|$  and  $P_d$  is the southward

**Table 5.** Fit parameters of the regression  $R_{\text{sd}}/R_E = A|B_{\text{IMF}}|^\alpha P_d^\beta$  and standard errors.

IMF	A	$\alpha$	$\beta$
Earth–Sun	40	−0.35	−0.16
	$\pm 8$	$\pm 0.04$	$\pm 0.02$
Northward	17.2	−0.196	−0.122
	$\pm 1.3$	$\pm 0.016$	$\pm 0.007$
Southward	20.2	−0.286	−0.175
	$\pm 1.6$	$\pm 0.016$	$\pm 0.008$
Ecliptic	19.2	−0.260	−0.143
	$\pm 1.8$	$\pm 0.019$	$\pm 0.008$

**Fig. 17.** Plot of the surface function  $R_{\text{sd}}/R_E = A|B_{\text{IMF}}|^\alpha P_d^\beta$  when the IMF is oriented in the (a) Earth Sun, (b) ecliptic ctr-clockwise, (c) southward, and (d) northward directions. The parameter  $T_{\text{sw}} = 1.8 \times 10^5$  K is fixed.

orientation. The simulations indicate that for  $P_d$  and  $|B_{\text{IMF}}|$  values consistent with extreme space conditions such as an ICMEs impacting the Earth ( $|B_{\text{IMF}}| \approx 100$  nT and  $P_d \approx 30$  nPa), there is no direct precipitation of the SW toward the Earth surface. The smallest  $R_{\text{sd}}/R_E = 2.92$  is obtained for the southward IMF orientation. In addition, super-CMEs with  $|B_{\text{IMF}}| = 250$  nT and  $P_d = 100$  nPa and an IMF oriented in the southward direction just lead to a  $R_{\text{sd}}/R_E$  slightly below 2.5, which is higher than 2.8 for the remaining IMF orientations. The balance between the dynamic pressure and IMF intensity is particularly complex for the Earth–Sun IMF orientation for simulations with  $P_d < 30$  nPa, leading to an increase in  $R_{\text{sd}}/R_E$  as  $|B_{\text{IMF}}|$  increases. This is caused by the North–South deformation that is induced at the DS and NS of the magnetosphere. On the other hand, simulations with  $P_d > 30$  nPa,  $R_{\text{sd}}/R_E$  show a weak dependence on  $|B_{\text{IMF}}|$  because the compression of the BS is partially counterbalanced by the North–South asymmetry induced in the magnetosphere.

Next,  $R_{\text{sd}}/R_E$  data were fit with respect to  $P_d$  and  $|B_{\text{IMF}}|$  by the surface function  $R_{\text{sd}}/R_E = A|B_{\text{IMF}}|^\alpha P_d^\beta$ . The regression results are indicated in Table 5 and Fig. 17. The regression analysis for the southward IMF orientation only includes  $P_d < 60$  nPa values, thus the simulations with  $R_{\text{sd}}/R_E < 2.5$  are not included in the study.

The expected exponents from the Eq. (6) are  $\alpha = -0.33$  and  $\beta = -0.17$ , although the regressions show clear deviations mainly caused by the Earth magnetic field reconnection with the IMF, particularly in the simulations with large  $|B|_{\text{IMF}}$ , as well as the pressure generated by the particles inside the BS in the simulations with low  $P_d$ . The largest deviation of the  $\alpha$  exponent is observed for the ecliptic and northward IMF orientation because there is a strong West-East tilt and poleward stretching induced in the magnetosphere that is further promoted in simulations with large  $P_d$ . In the southward IMF orientation, the  $\alpha$  exponent is smaller than the theoretical value because of the erosion induced in the Earth magnetic field at the equatorial region. On the other hand, the Earth–Sun IMF orientation shows an  $\alpha$  exponent that is closer to the theoretical value because the induced northward bending of the magnetosphere is weaker as the simulation  $P_d$  increases. The  $\beta$  exponent of the regressions agrees reasonably well with the theoretical exponent, although the deviation is significant regarding the ecliptic and northward IMF orientation cases for the reasons already mentioned.

In conclusion, the SW dynamic pressure, IMF intensity, and orientation are the main parameters required to study the response of the Earth magnetosphere to space weather conditions. Thus, the trends of the topological deformations identified by the parametric study can be generalized, providing a new tool for analyzing the consequences of the magnetosphere distortion. This is the topic of the following section.

#### 4. Analysis applications

This section shows several applications of the study conclusions. Particularly, the direct exposition of satellites in different orbits to the SW for different space weather conditions, the Earth habitability along the solar main sequence, and an ICME classification with respect to the  $|B|_{\text{IMF}}$ ,  $P_d$ , and  $Dst$  parameters.

##### 4.1. Forecast of space weather conditions for the SW precipitation toward the Earth surface

Figure 18 shows the critical  $|B|_{\text{IMF}}$  required for the direct precipitation of the SW toward the Earth surface with respect to  $P_d$  and the IMF orientation. The SW precipitates directly toward the Earth surface if the magnetopause standoff distance of the simulation is the same as the Earth radius. Thus, the critical  $|B|_{\text{IMF}}$  is calculated from the regression parameters taking  $R_{\text{sd}}/R_E = 1$ , thus  $\ln(|B|_{\text{IMF,c}}) = \ln[(AP^\beta)^{-1}]/\alpha$ .

The direct precipitation of the SW requires the combination of extreme  $P_d$  and  $|B|_{\text{IMF}}$  values well above the space weather conditions at the Earth even during super-ICME. For example, a southward IMF orientation with  $|B|_{\text{IMF}} = 1000$  nT requires  $P_d \geq 355$  nPa, while an Earth–Sun IMF orientation requires  $P_d \geq 3660$  nPa, which is 5–4 times larger than a super-ICME. Ecliptic and northward IMF orientations require even larger  $|B|_{\text{IMF}}$  and  $P_d$  combinations for the direct precipitation of the SW.

##### 4.2. Space weather conditions for the direct exposition of satellites to the solar wind

The direct exposition to the SW can inflict failure of the satellite electronics by radiation damage and charging. The Earth magnetic field protects the spacecraft, although the distortion of the magnetosphere driven by space weather conditions can lead to excursions outside the inner magnetosphere along the satellite orbit, particular at the Earth DS, where the magnetosphere is compressed by the SW and eroded by the IMF.

**Fig. 18.** Critical  $|B|_{\text{IMF}}$  required for the direct precipitation of the SW toward the Earth surface with respect to  $P_d$  and the IMF orientation. Fixed  $T_{\text{sw}} = 1.8 \times 10^5$  K. IMF direction: Earth–Sun (red circle), southward (green triangle), and ecliptic ctr-clockwise (cyan pentagon).

Consequently, it is important to analyze the space weather conditions that can lead to the direct exposition of satellites at different orbits to the SW. The satellite orbits around the Earth are classified into low orbits (below 2000 km), medium orbits (between 2000–35 786 km), geosynchronous and geostationary orbits (at 35 786 km), and high orbits (above 35 786 km). Figure 19 indicates the critical  $P_d$  for different IMF intensities and orientations required to reduce the magnetopause standoff distance below the geostationary orbit  $R_{\text{go}} = R/R_E \approx 6.6$  (panel a) and medium orbits at  $R_{\text{mo}} = R/R_E = 4.125$  (20 000 km, panel b) and 2.5625 (10 000 km, panel c).

For the satellites on a geostationary orbit (panel a), during regular space weather conditions with  $P_d \approx 1$  nPa there is a transit outside the inner magnetosphere at the Earth DS if the IMF orientation is Earth–Sun and  $|B|_{\text{IMF}} > 150$  nT, decreasing to 130 nT for a northward IMF. The  $|B|_{\text{IMF}}$  decreases to 50–60 nT if the IMF is southward or ecliptic ctr-cw. That is to say, southward and ecliptic IMF orientations are adverse for geostationary satellites because  $R_{\text{sd}}/R_E$  decreases below  $R_{\text{go}}$  due to the erosion of the magnetic field at the DS and the East–West asymmetry driven in the magnetosphere. Likewise, if the space weather conditions lead to an enhancement of  $P_d$ , the geostationary satellites are exposed for southward IMF with  $|B|_{\text{IMF}} = 10$  nT and  $P_d \approx 14$  nPa, as well as ecliptic IMF with  $|B|_{\text{IMF}} = 10$  nT and  $P_d \approx 26$  nPa.

On Earth medium orbits, a satellite at 20 000 km is exposed during regular space weather conditions with  $P_d \approx 1$  nPa if  $|B|_{\text{IMF}} > 260$  nT for a southward IMF,  $|B|_{\text{IMF}} > 360$  nT for an ecliptic IMF,  $|B|_{\text{IMF}} > 600$  nT for an Earth–Sun IMF and  $|B|_{\text{IMF}} > 1450$  nT for a northward IMF. Consequently, satellites on orbits of 20 000 km and lower are protected by the magnetosphere during regular space weather conditions because the critical  $|B|_{\text{IMF}}$  is too large. On the other hand, extreme space weather conditions lead to exposed satellites at 20 000 km for southward IMF with  $|B|_{\text{IMF}} = 40$  nT and  $P_d \approx 20$  nPa, ecliptic IMF with  $|B|_{\text{IMF}} = 40$  nT, and  $P_d \approx 55$  nPa, Earth–Sun IMF with  $|B|_{\text{IMF}} = 100$  nT and  $P_d \approx 60$  nPa, as well as northward IMF with  $|B|_{\text{IMF}} = 100$  nT and  $P_d \approx 70$  nPa. In addition, satellites on an orbit of 10 000 km are only exposed if the IMF is southward,  $|B|_{\text{IMF}} = 100$  nT and  $P_d \approx 70$  nPa.

**Fig. 19.** Critical  $P_d$  to reduce the magnetopause standoff distance below (a) the geostationary orbit (b) medium orbit at  $R_{mo} = R/R_E = 4.125$  and (c) medium orbit at 2.5625 for different IMF intensities and orientations. Fixed  $T = 1.8 \times 10^5$  K. IMF direction: Earth–Sun (red circle), northward (blue diamond), southward (green triangle), and ecliptic counter-clockwise (cyan pentagon).

#### 4.3. ICME classification

Most of the ICMEs that impact the Earth, around 1000 in each solar cycle, show an averaged plasma velocity lower than  $500 \text{ km s}^{-1}$  and IMF intensities below 15 nT. This leads to geomagnetic storms with  $Dst < -50$  nT (Cane & Richardson 2003). Super-ICME events similar to the Carrington event are less frequent. They occur about once in each century (Riley et al. 2018),

**Table 6.** ICME classification with respect to the SW dynamic pressure, IMF intensity, and  $Dst$  parameter.

ICME type	$P_d$ (nPa)	$ B _{IMF}$ (nT)	$Dst$ (nT)
Common	$<40$	$<50$	$> -50$
Strong	$[40, 100]$	$[50, 100]$	$[-50, -200]$
Super	$>100$	$>100$	$< -200$

although the potential damage in space and ground technological resources is large (Baker et al. 2013; Eastwood et al. 2017, 2018). Other examples of super-ICME that did not impact the Earth were analyzed by Liu et al. (2014) using STEREO data, indicating plasma velocities about  $2000 \text{ km s}^{-1}$ , a density of  $100 \text{ cm}^{-3}$  ( $P_d \approx 330$  nPa), and  $|B|_{IMF} \approx 100$  nT ( $Dst = -600$  to  $-1100$  nT). Space weather conditions during ICMEs can also be modeled using ENLIL (Odstrcil & Pizzo 1999; Odstrcil et al. 2002), the European Heliospheric FORecasting Information Asset (EUHFORIA; Pomoell & Poedts 2018), and the Susanoo model (Shiota & Kataoka 2016), among others. Combining satellite data and modeling results, a classification of the ICMEs is proposed in Table 6 with respect to the SW dynamic pressure, IMF intensity, and  $Dst$  parameter.

When the results of our study are analyzed in the context of the proposed ICME classification, the direct precipitation of the SW toward the Earth surface is very unlikely, even for the case of super-ICMEs. The direct SW precipitation during a super-ICME for a southward IMF orientation requires extreme space weather condition values well above the expected range of the  $P_d$  and  $|B|_{IMF}$  values, as was discussed in previous sections. Nevertheless, extreme space weather conditions inside the category of strong ICMEs already lead to magnetopause standoff distances of about  $R_{sd}/R_E \approx 2.5$  if  $P_d = 60$  nPa and  $|B|_{IMF} = 100$  nT for a southward IMF orientation,  $R_{sd}/R_E \approx 3.8$  for an Earth–Sun IMF orientation,  $R_{sd}/R_E \approx 3.2$  for an ecliptic IMF orientation, and  $R_{sd}/R_E \approx 4.1$  for a northward IMF orientation. Consequently, strong ICMEs are a threat to satellites on geostationary, high, and medium orbits. In particular the geostationary satellites are above the magnetopause for all the range of space weather condition inside the strong ICME category and IMF orientations. In addition, the medium-orbit satellites at 20 000 km are above the magnetopause if the IMF is southward for all the range of space weather condition inside the strong ICME category. It should be noted that medium-orbit satellites at 20 000 km are inside the inner magnetosphere if the IMF is northward during strong ICME space weather conditions. Medium-orbit satellites at 10 000 km are protected by the magnetosphere during strong ICME space weather conditions, although they are exposed to the direct impact of the SW during super-ICME space weather conditions in particular for the southward IMF orientation.

#### 4.4. Earth habitability during the early-Sun main sequence

This section is dedicated to the analysis of the Earth habitability with respect to the space weather conditions during the solar evolution on the main sequence. Early stages of the solar evolution are linked to a faster rotation rate and higher magnetic activity (Emeriau-Viard & Brun 2017) because the solar rotation and magnetic activity decrease during the main sequence (Folsom et al. 2017; Fabbian et al. 2017). Consequently, the space

**Table 7.** Averaged magnetopause standoff distance for a southward IMF during regular space weather condition with respect to  $\Omega_S$ .

IMF	$R_{sd}/R_E$ ( $2\Omega_S$ )	$R_{sd}/R_E$ ( $5\Omega_S$ )	$R_{sd}/R_E$ ( $10\Omega_S$ )
Earth–Sun	10	4.1	2.2
	$\pm 2$	$\pm 0.8$	$\pm 0.4$
Northward	7.1	4.1	2.8
	$\pm 0.5$	$\pm 0.3$	$\pm 0.2$
Southward	5.6	2.5	1.44
	$\pm 0.4$	$\pm 0.2$	$\pm 0.11$
Ecliptic	6.4	3.2	1.94
	$\pm 0.6$	$\pm 0.3$	$\pm 0.18$

**Notes.** Standard error of the regression parameters and derived  $R_{sd}/R_E$  uncertainty are included.

weather conditions change (Réville et al. 2016; Carolan et al. 2019; Ahuir et al. 2020). When we consider the rotation tracks from Carolan et al. (2019) (Table 1), the average values of the SW radial velocity, density, and radial IMF intensity for different solar rotation rates are provided, thus the effect of the space weather conditions on the Earth magnetosphere during different stages of the solar evolution on the main sequence can be studied in the first approximation. The actual rotation rate of the Sun ( $\Omega_S$ ) decreased from  $10\Omega_S$  to  $2\Omega_S$  between the first 300 to 1100 Myr of the solar evolution. The SW density approximately decreased from 1000 to  $140\text{ cm}^{-3}$ , the radial velocity from 1100 to  $700\text{ km s}^{-1}$  ( $P_d$  drops from 980 to 57 nPa), and  $|B|_{\text{IMF}}$  from 150 to 7 nT. Table 7 shows the averaged magnetopause standoff distance for a southward IMF during regular space weather condition with respect to  $\Omega_S$  based on the parametric study ( $R_{sd}/R_E = A|B|_{\text{IMF}}^\alpha P_d^\beta$ ). The uncertainty of  $R_{sd}/R_E$  is calculated as  $\Delta(R_{sd}/R_E) = |B|_{\text{IMF}}^\alpha P_d^\beta \Delta A + \alpha A P_d^\beta |B|_{\text{IMF}}^{\alpha-1} \Delta \alpha + \beta A |B|_{\text{IMF}}^\alpha P_d^{\beta-1} \Delta \beta$ .

The analysis results indicate that the Earth magnetosphere avoids the direct precipitation of the SW during regular space weather condition if  $\Omega = 5\text{--}10\Omega_S$ , consistent with Carolan et al. (2019) analysis. Nevertheless, super-CMEs during the early main sequence of the Sun were probably more frequent, intense, and lasted longer (two or three days) (Sternborg et al. 2011; Airapetian et al. 2015a,b), as the detection of superflares by *Kepler* mission for main-sequence G-K stars suggests (Shibayama et al. 2013). Figure 20 shows the range of parameters required for the direct precipitation of the SW during regular and CME space weather conditions on the early main sequence of the Sun ( $\Omega = 5\text{--}10\Omega_S$  and  $<440\text{ Myr}$ ). For simplicity, the space weather conditions consistent with CMEs on the solar early main sequence are in the range of 1 to 20 times the averaged  $P_d$  and  $|B|_{\text{IMF}}$  values provided by Carolan et al. (2019). Only the data for southward IMF orientations are shown. They lead to the most restrictive space weather conditions.

The analysis shows a possible direct precipitation of the SW during early phases of the solar main sequence for CME-like space weather conditions, particularly if the solar rotation rate is  $10\Omega_S$ . This indicates a wide range of parameters that lead to  $R_{sd}/R_E < 1$ .

In summary, the emerging life at the Earth surface was protected from the sterilizing effect of the SW during regular and CME-like space weather conditions 1100 Myr after the Sun entered the main sequence. On the other hand, during the first 440 Myr of the solar main sequence, CMEs and super-CMEs were a major hazard for Earth habitability, especially due to the

**Fig. 20.** Critical  $P_d$  and  $|B|_{\text{IMF}}$  values for the direct precipitation of SW toward the Earth surface for a southward IMF if (a)  $5\Omega_S$  and (b)  $10\Omega_S$ . The dashed gray region indicates the space weather conditions that lead to the direct precipitation of the SW toward the Earth surface. The dashed orange region shows the regular space weather conditions. The parameter  $T = 1.8 \times 10^5\text{ K}$  is fixed.

high recurrence and prevalence of extreme space weather conditions. Our study results are comparable with the studies by See et al. (2014); Airapetian (2016).

#### 4.5. Simulation of ICMEs impacting Earth between 1997 and 2020

A set of simulations was performed to reproduce the space weather conditions during the ICMEs that reached Earth between 1997 and 2020. The CMEs included in the analysis are a subsample of the CME Richardson list (Richardson & Cane 2020). We selected the most extreme events with respect to the  $P_d$  and  $|B|_{\text{IMF}}$  values. They are listed in Appendix D. In the proposed ICME classification, all the events are common ICMEs, except for the space weather conditions on 16/07/2000 and 24/11/2001, which are close to the strong ICME category ( $P_d \approx 30\text{ nPa}$  and  $|B|_{\text{IMF}} \approx 50\text{ nT}$ ). Table 8 indicates the location of the nose of the BS, magnetopause standoff distance, and the lowest OCB latitude at the DS and NS in the North and South Hemispheres for the ICMEs we analyzed. In addition, the  $K_p$

**Table 8.** ICME date (first column), magnetopause, and BS standoff distance (second column), OCB minimum in the North and South Hemispheres on the DS (third column) and NS (fourth column), and  $K_p$  index derived from the lowest OCB line latitude at the North Hemisphere (fifth column).

Date (dd/mm/yyyy)	$\frac{R_{sd}}{R_E}, \frac{R_{BS}}{R_E}$	OCB N–S DS (lat °)	OCB N–S NS (lat °)	$K_p$

29/05/2003	3.38 – 5.52	55 – 56	56 – 55	6
24/10/2003	4.09 – 6.75	58 – 58	58 – 57	5
20/11/2003	4.29 – 11.66	54 – 55	56 – 55	7
07/11/2004	3.48 – 6.80	60 – 60	58 – 59	5
21/01/2005	3.75 – 5.27	55 – 55	56 – 56	6
15/05/2005	3.88 – 6.59	54 – 54	55 – 55	7
24/08/2005	3.52 – 6.63	53 – 53	55 – 54	7
24/10/2011	5.82 – 9.15	56 – 56	56 – 56	6
13/11/2012	5.10 – 7.98	57 – 58	58 – 58	5
17/03/2015	5.30 – 8.49	57 – 58	58 – 58	6
03/08/2016	6.91 – 12.53	58 – 58	58 – 58	5
27/05/2017	5.33 – 7.74	58 – 58	58 – 58	5
16/07/2017	5.53 – 9.11	57 – 58	59 – 58	5
20/04/2020	5.94 – 8.80	59 – 60	60 – 58	4

index was calculated from the lowest latitude of OCB line in the North Hemisphere. The IMF and SW values we used as the simulation input represent the combination of SW dynamic pressure, IMF module, and southward IMF component that causes the strongest disturbance of the Earth magnetosphere during the ICME, but not necessarily the highest dynamic pressure, IMF module, and southward IMF component because these maxima may occur at different times. Figures D.1 and D.2 show the 24-h evolution of the IMF module and components, the velocity module and radial component, as well as the SW density and temperature for 15/05/1997 and 31/03/2001. The model resolution in the latitudinal direction is doubled, reducing the uncertainty of the OCB line from 4° to 2°, thus the uncertainty of the calculated  $K_p$  index is  $\pm 1$ .

The ICMEs that led to the smallest magnetopause standoff distance impacted the Earth on 24/11/2001 and 29/05/2003 with  $R_{sd}/R_E < 3.4$ . The lowest OCB latitudes in the North and South Hemispheres,  $< 53^\circ$ , were observed for the ICMEs on 31/03/2001*b*, 24/11/2001, 15/05/2005, and 24/08/2005, that is to say, the North of Canada, Alaska, North of Russia, and in the Nordic countries (except for continental Denmark) are exposed to plasma precipitation along the open magnetic fields. The calculated  $K_p$  index derived from the lowest OCB line latitude in the North Hemisphere is consistent with the measured  $K_p$  considering the  $\pm 1$  uncertainty, except for the 29/05/2003 ICME, for which the calculated  $K_p$  index is two units smaller than the measured index. The aurora is generated by the electrons and ions precipitating toward the Earth surface, thus the plasma flows in the simulations must also be analyzed. Figure 21 indicates the plasma flows and velocity isocontours of the inflow regions at  $R/R_E = 2.75$  for ICMEs on 31/03/2001*b*, 24/11/2001, 15/05/2005, and 24/08/2005 (ICMEs with the

**Table 9.** ICME date (first column), plasma flow latitude at the DS North Hemisphere (second column) and South Hemisphere (third column), NS North Hemisphere (fourth column) and South Hemisphere (fifth column), and inflow plasma velocity  $\geq 100 \text{ km s}^{-1}$ .

Date (dd/mm/yyyy)	DS N (lat °)	DS S (lat °)	NS N (lat °)	NS S (lat °)
31/03/2001 <i>b</i>	52–63	52–66	55–62	54–61
24/11/2001	51–66	51–72	55–63	55–63
21/01/2005	51–69	51–74	55–62	56–63
24/08/2005	50–62	50–66	54–63	55–62

largest observed  $K_p = 8$  index). In addition, Table 9 shows the latitude of the plasma flow extrapolated to the Earth surface in the North and South Hemispheres (inflow plasma velocity  $\geq 50 \text{ km s}^{-1}$ ).

The simulations indicate the formation of plasma streams connecting the magnetosheath and the Earth surface (see Fig. 21, blue and isolines). Regarding the IMF orientation, the inflow plasma regions on the Earth DS show an East–West asymmetry caused by the large IMF component on the ecliptic plane, for example, for the 24/11/2001 ICME, or a North–South asymmetry due to the IMF component on the Sun–Earth direction, for example, for the 24/08/2005 ICME. When the plasma flows are extrapolated to the Earth surface ( $v \geq 50 \text{ km s}^{-1}$ , cyan line isolate), the plasma streams are deposited on the planet DS between the latitudes 50–74°. The simulation of the 24/08/2005 ICME shows the plasma deposition in the lowest latitude at the North Hemisphere DS 50–62°, although the simulation of the 21/01/2005 ICME indicates the widest plasma deposition region at the North Hemisphere DS 51–69°. Consequently, the plasma streams scatter from the OCB line and are deposited at the Earth surface from lower latitudes (between 2–3° below the OCB line latitude). If the  $K_p$  index is calculated including the scattering of the plasma streams, the  $K_p$  index for the simulations analyzed is 8, the same value as the measured  $K_p$  index. Regarding the plasma flows towards the Earth NS, the inflow maximum ( $v \geq 200 \text{ km s}^{-1}$ , dark blue isolate) is observed between 54–56° latitude, consistent with the latitude of the aurora observations during extreme space weather conditions (Shaw 2019; Hayakawa et al. 2018; Mikhalev 2019). The plasma flows for the remaining ICME simulations is lower than that of the highlighted cases.

Figure 22 shows the OCB line calculated for the 27/05/2017 ICME simulations and the energy flux calculated by Ovation Prime simulations for 27/05/2017  $t = 22 : 00$  hours in the North and South Hemisphere. The Ovation Prime model is used to forecast the latitude and longitude of the visible aurora (Newell et al. 2010; Machol et al. 2012). Ovation prime data are provided by the integrated Space Weather Analysis system (iSWA; iSW 2020).

The latitude of the OCB line on the Earth NS is located between 58–64° in the North Hemisphere and 59–65° in the South Hemisphere, similar to the Ovation prime forecast of the aurora location that indicates a local maxima of the energy flux between latitudes 58–65°. In addition, the  $K_p$  index derived from the OCB line is 5, which is the same value as the measured  $K_p$  index on 27/05/2017 at  $t = 22 : 00$  h.

Figure 23 shows the satellites at geosynchronous, high, medium, and low orbits around the Earth with respect to the location of the BS nose and magnetopause standoff distance calculated from the ICME simulation results, in particular for the

**Fig. 21.** Plasma flow (color surfaces  $10^{-16} \text{ kg m}^{-3}$ ) at  $R/R_E = 2.75$  for ICMEs that impacted Earth on (a) 31/03/2001b, (b) 24/11/2001, (c) 15/05/2005, and (d) 24/08/2005. Velocity isocontours at  $50 \text{ km s}^{-1}$  (light cyan),  $100 \text{ km s}^{-1}$  (yellow),  $150 \text{ km s}^{-1}$  (orange), and  $200 \text{ km s}^{-1}$  (red).

**Fig. 22.** (a) OCB line calculated from the 27/05/2017 ICME simulation. Energy flux calculated by Ovation prime simulations at the (b) North Hemisphere and (c) South Hemisphere. Ovation prime data are provided by the iSWA (iSW 2020).

**Fig. 23.** Schematic view of the satellites at geosynchronous, high, medium, and low orbits around the Earth between 2000–2020. The orbits highlighted by red dots are geosynchronous satellites. The solid pink lines indicate orbits at  $R/R_E = i$  with  $i$  an integer between 2 to 8 ( $R_i$ ). The dashed pink line indicates the geosynchronous orbit ( $R_g$ ). The colored symbols and horizontal lines show the standoff distance of the magnetopause and the BS nose for the different ICMEs we analyzed: light green star for 22/10/1999, light cyan star for 16/07/2000, light pink star for 31/03/2001b, light gray star for 24/11/2001, yellow diamond for 29/05/2003, cyan diamond for 24/10/2003, pink diamond for 07/11/2004, gray diamond for 21/01/2005, orange triangle for 15/05/2005, and blue triangle for 24/08/2005.

space weather conditions leading to the smallest magnetopause standoff distance that threatens the satellite integrity by direct exposition to the SW.

The space weather conditions for the 16/07/2000, 31/03/2001b, 24/11/2001, 29/05/2003, 21/01/2005 and 15/05/2005 ICMEs lead to  $R_{BS} < R_{go}$ , that is to say, the geosynchronous satellites directly face the SW during a fraction

of the orbit on the Earth DS. Consequently, the integrity of geosynchronous satellites is in danger, especially because of the high SW density, up to  $50 \text{ cm}^{-3}$ . On the other hand, the space weather conditions during the 03/08/2016 ICMEs led to  $R_{sd} > R_{go}$ , thus the geosynchronous satellites are inside the Earth inner magnetosphere during the full orbit. The space weather conditions during the remaining ICMEs we analyzed show a  $R_{BS} > R_{go} > R_{sd}$ , thus the geosynchronous satellites are inside the Earth magnetosphere during the full orbit, although for a fraction of the orbit on the DS, the satellites cross the magnetosheath and enter the BS. Inside the BS, the SW particles slow down and accumulate, leading to a decrease in protection from the magnetosphere. The model developed by [Dmitriev et al. \(2016\)](#) predicted the magnetopause crossing of geosynchronous satellite during the 20/11/2003, 07/11/2004, 15/05/2005 and 24/08/2005 ICMEs, consistent with simulation results that indicate a magnetopause standoff distance below the geosynchronous satellite orbit: 4.29, 3.48, 3.88, and 3.52  $R_E$ , respectively. In addition, observations of magnetopause crossings by the geosynchronous satellite 1991 – 080, 1994 – 084 and LANL – 01A during 31/03/2001 ICME ([Ober et al. 2002](#)), by GOES 13 – 15 and MMS during 17/03/2001 ICME ([Le et al. 2016](#)), by THEMIS A and E during 27/05/2017 ICME ([Pezzopane et al. 2019](#)) are reported. They are also consistent with the simulation results, which predict a magnetopause standoff distance of 4.01, 5.30, and 5.33  $R_E$ , respectively. The satellites on medium orbits below 10 000 km are inside the magnetosphere throughout the full orbit for all the ICMEs we analyzed, although medium orbits on 20 000 km crossed the magnetosheath during the 22/10/1999, 31/03/2001, 24/10/2003, 07/11/2004, and 24/08/2005 ICMEs. Examples of the consequences of the severe space weather conditions during the 24/10/2003 ICME are the loss of the low-orbit satellite ADEOS/MIDORI 2 due to electrostatic discharge, the engine switch-off of the high-orbit satellite SMART-1 caused by the ionization effect of the SW, two weeks outage of the geostationary satellite DRTS/Kodama that was also caused by electrostatic discharge, as well as high bit error rates and magnetic torques that disabled GOES 9, 10, and 12 ([Tamaoki et al. 2010](#); [Cannon et al. 2013](#)). The simulation of the 24/10/2003 ICME predicts a minor-moderate auroral activity, a significant East–West tilt of the Earth magnetosphere, and a relatively short magnetopause standoff distance ( $R_{sd}/R_E = 4.09$ ).

## 5. Discussion and conclusions

The distortion induced by the SW and the IMF on the topology of the Earth magnetosphere must be analyzed in detail because the large variability of the space weather conditions triggers a wide number of physical phenomena, for example, geomagnetic storms. Extreme space weather conditions have consequences for the integrity of satellites orbiting the Earth, electric power grids, and human health. In addition, an efficient shielding of the exoplanet magnetic field to avoid the direct precipitation of the stellar wind toward the surface is critical for exoplanet habitability.

Simulating the interaction of the SW and IMF with the Earth magnetic field using MHD models is a useful tool for analyzing the global structures of the magnetosphere during different space weather conditions. The validity of the MHD models was confirmed by comparing simulation results and spacecraft- and ground-based measurements ([Watanabe & Sato 1990](#); [Raeder et al. 2001](#); [Wang et al. 2003a](#); [Facsó et al. 2016](#); [Honkonen et al. 2013](#)). Consequently, a parametric analysis based on MHD

simulations regarding the SW density, velocity, and temperature as well as the IMF orientation and intensity may provide a reasonable first approximation of the space weather effects on the topology of the Earth magnetosphere. We recall that no kinetic effects are included in the study, thus deviations between simulation results and observational data can exist for some of the extreme space weather configurations we analyzed.

The set of simulations we performed for which we fixed the SW dynamic pressure, but modified the IMF orientation and intensity show the critical role of the IMF on the topology of the Earth magnetosphere. It leads to a large variation in the magnetopause standoff distance, the location of the reconnection regions between the IMF and the Earth magnetic field where the SW is injected inside the inner magnetosphere, the plasma streams between the magnetosheath and the Earth surface as well as the open and closed field line boundary. Particularly the southward, Sun–Earth, and Earth–Sun IMF orientations lead to the smallest magnetopause standoff distances as the IMF intensity increases. In addition, the reconnection regions are closer to the Earth surface as the IMF intensity increases, although at different locations inside the magnetosphere regarding the IMF orientation. This modifies the plasma flows toward the Earth surface. In the same way, an intense IMF oriented in the southward direction causes a decrease in latitude of the OCB, exposing wider regions of the Earth surface to the plasma flows along the magnetic field lines. For example, the OCB on the DS ( $0^\circ$  longitude) decreases from  $72$  to  $53^\circ$  when simulations without an IMF and with a southward IMF with 250 nT are compared. The results of the parametric study are consistent with those of other authors regarding the magnetopause standoff distance ([Song et al. 1999](#); [Kabin et al. 2004](#); [Lavraud & Borovsky 2008](#); [Ridley et al. 2010](#); [Meng et al. 2012](#); [Wang et al. 2015](#)) and the latitude of the OCB ([Lopez et al. 1999](#); [Kabin et al. 2004](#); [Wild et al. 2004](#); [Rae et al. 2004](#); [Wang et al. 2016](#); [Burrell et al. 2020](#)).

The simulations indicate that the direct precipitation of the SW toward the Earth surface is very unlikely in the range of space weather conditions expected for current and future stages of the Sun in the main-sequence evolution. The extreme space weather conditions during ICME and super-ICME impacting the Earth cannot lead to a compression and erosion of the Earth magnetosphere that would be large enough to reduce the magnetosphere standoff distance below  $R_{sd}/R_E = 1$ . For example, the SW precipitation toward the Earth surface for an IMF that is purely oriented in the southward direction requires an IMF intensity of 1000 nT and a SW dynamic pressure above 350 nPa, space weather conditions well above super-ICMEs. In addition, if the analysis is extended to previous stages of the solar evolution, the simulations show an efficient shielding of the Earth surface 1100 Myr after the Sun enters the main sequence. On the other hand, early evolution stages when the solar rotation rate was 5–10 times faster than the current rotation rate, the case of the first 440 Myr of the solar main sequence, the Earth habitability could be threatened during extreme space weather conditions. These results are consistent with the studies of [See et al. \(2014\)](#); [Airapetian \(2016\)](#). The Earth magnetic field intensity is a fixed parameter in the analysis, although several studies indicated that the Earth magnetic field might be stronger during early evolution phases of the solar system ([Tarduno et al. 2007, 2010, 2020](#)). In addition, there are other factors that affect the young Earth habitability that we did not include in the study, for example, the solar luminosity and X-ray or ultraviolet emission ([Cockell 2001](#); [Sackmann & Boothroyd 2003](#); [Ribas et al. 2005](#); [Cnossen et al. 2007](#)) or the atmospheric evolution ([Kasting & Catling 2003](#); [Arndt & Nisbet 2012](#); [Gronoff et al. 2020](#)). Consequently,

supplementary analyses are required to confirm the habitability of the young Earth. This will be the topic for a future research.

An ICME classification for the Earth is proposed regarding the SW dynamic pressure, IMF intensity, and Disturbance Storm Time Index. The ICME classification consists of three categories: common, strong, and super-ICMEs. Common ICMEs have a relatively fast recurrence and cover the main number of extreme space weather events impacting the Earth with SW dynamic pressures  $<40$  nPa, IMF intensities  $<50$  nT, and  $Dst < -100$  nT. Strong ICMEs have a lower recurrence, a few events each year, particularly associated with the maximum of the solar magnetic activity cycle, showing a dynamic pressure in the range of  $[40, 100]$  nPa, an IMF intensity of  $[50, 100]$  nT, and  $Dst = [-100, -500]$  nT. The super-ICME category identifies events that occur once per century, similar to the Carrington event with an SW dynamic pressure above 100 nPa, an IMF intensity above 100 nT, and  $Dst > -500$  nT. This classification is consistent with those in the studies of other authors (Rastatter et al. 2002; Tsurutani et al. 2003; Siscoe et al. 2006; Saiz et al. 2008; Balan et al. 2014; Keika et al. 2015).

The simulations we performed to reproduce the effect of the ICMEs impacting the Earth between 1997 – 2020 indicate that all the events can be included in the common ICME category, except for the extreme space weather conditions observed on 16/07/2000 and 24/11/2001. These are classified as close to the strong ICME category ( $P_d \approx 30$  nPa and  $|B|_{IMF} \approx 50$  nT). The event on 29/10/2003 was not included in the study because of the lack of SW and IMF data, although this event probably belongs to the strong ICME category (Balan et al. 2014). For example, the Earth magnetosphere distortion during the 24/11/2001 ICME was large enough to potentially impact the electric grids of the North of Canada, Alaska, the North of Russia, and the Nordic countries (except for continental Denmark). In addition, the  $K_p = 8$  index calculated regarding the plasma flows toward the Earth surface is the same as the  $K_p = 8$  index we measured.

We recall that the simulations neglect the effect imprinted on the Earth magnetosphere by previous space weather conditions. Consequently, the simulations performed for ICMEs showing a fast variation in space weather conditions could overestimate the forcing of the SW and IMF. This is the case of the simulations performed for the 31/03/2001 ICME; see Fig. D.2. It shows large variations in IMF orientation and intensity as well as SW dynamic pressure within a time frame of minutes. On the other hand, the space weather parameters are quasi-steady within a time frame of 1 h during the 15/05/1997 ICME; see Fig. D.1. The simulation results are therefore more accurate.

Although no direct SW precipitation is expected toward the Earth surface, extreme space weather conditions can endanger the integrity of the satellites around the Earth because the magnetopause standoff distance decreases and the satellite orbit on the Earth DS is partially unprotected outside the magnetosphere. Southward and ecliptic IMF orientations are particularly adverse for geosynchronous satellites, which are partially exposed to the SW if the SW dynamic pressure is  $\approx 14$ – $26$  nPa and the IMF intensity 10 nT, that is to say, 5–10 times the dynamic pressure of regular space weather conditions. On the other hand, medium-orbit satellites at 20 000 km are directly exposed to the SW during common ICMEs if the IMF orientation is southward and during strong ICMEs if the IMF orientation is Earth–Sun or ecliptic. In the same way, medium-orbit satellites at 10 000 km are directly exposed to the SW if a super-ICME with a southward IMF orientation impacts the Earth. For example, during the ICMEs on 15/07/2000, 24/11/2001, 29/05/2003,

and 21/01/2005, the geosynchronous satellites were directly affected by the SW during a fraction of the orbit on the Earth DS, although medium-orbit satellites below  $R/R_E \approx 5$  were protected by the magnetosphere during the full orbit. Other important threats to the satellite integrity during extreme space weather conditions, such as the enhancement of the Earth radiation belts and the atmosphere drag force, are not included in the study.

## Appendix A: Upper ionosphere model

The upper ionospheric domain is located between  $R = 2 - 2.5R_E$  in simulations with  $P_d > 1$  nPa and between  $R = 3 - 3.5R_E$  in simulations with  $P_d < 1$  nPa. The upper ionosphere model is based on (Büchner et al. 2003). Below the lower boundary of the upper ionosphere, the magnetic field intensity is too high, thus the simulation time step is too small. In addition, a single-fluid MHD model cannot correctly reproduce magnetosphere regions such as the inner ionosphere or the plasma sphere because the kinetic effects are strong.

First, the field-aligned current ( $J_{FAC}$ ) is calculated as

$$\mathbf{J}_{FAC} = \mathbf{J} - \mathbf{J}_\perp, \quad (\text{A.1})$$

where

$$\mathbf{J} = \frac{1}{\mu_0} \nabla \times \mathbf{B} \quad (\text{A.2})$$

$$\mathbf{J}_\perp = \mathbf{J} - \frac{J_r B_r + J_\theta B_\theta + J_\phi B_\phi}{|\mathbf{B}|^2} \mathbf{B}, \quad (\text{A.3})$$

with  $\mathbf{J}$  the plasma current,  $\mathbf{J}_\perp$  the perpendicular component of the plasma current along the magnetic field line,  $\mu_0$  the vacuum magnetic permeability, and  $\mathbf{B}$  the magnetic field.

Next, the electric field of the upper ionosphere model is calculated using the Pedersen conductance ( $\sigma$ ) empirical formula,

$$\sigma = \frac{40E_0 \sqrt{F_E}}{16 + E_0^2}, \quad (\text{A.4})$$

with  $E_0 = K_B T_e$  the mean energy of the electrons,  $F_E = n_e \sqrt{E_0} / (2\pi m_e)$  the energy flux, and  $K_B$  the Boltzmann constant ( $T_e$  and  $m_e$  are the electron temperature and mass, respectively). Thus, the electric field ( $E$ ) linked to the FAC is

$$\mathbf{E} = \sigma \mathbf{J}_{FAC}. \quad (\text{A.5})$$

When the electric field is calculated, the velocity of the plasma in the upper ionosphere is

$$\mathbf{v} = \frac{\mathbf{E} \times \mathbf{B}}{|\mathbf{B}|^2}. \quad (\text{A.6})$$

The plasma density in the upper ionosphere is defined with respect to the Alfvén velocity. The module of the Alfvén velocity is fixed ( $v_A = 8 \cdot 10^3$  km/s) to control the simulation time step, thus the density profile between  $R = 2 - 2.5R_E$  does not evolve during the simulation, defined as

$$\rho = \frac{|\mathbf{B}|^2}{\mu_0 v_A^2}. \quad (\text{A.7})$$

The plasma pressure in the upper ionosphere model is defined with respect to the sound speed of the SW ( $c_{sw}$ ) and at the inner boundary ( $c_p$ ),

$$p = \frac{n}{\gamma} \left( \frac{(c_p - c_{sw})(r^3 - R_s^3)}{R_{in}^3 - R_s^3} + c_{sw} \right)^2, \quad (\text{A.8})$$

with  $\gamma = 5/3$  the polytropic index,  $c_p = \sqrt{\gamma K_B T_p / m_p}$  with  $T_p$  is the plasma temperature at the inner boundary, and  $c_{sw} = \sqrt{\gamma K_B T_{sw} / m_p}$  with  $T_{sw}$  the SW temperature. Figure C.1 shows

**Fig. A.1.** Radial profiles of the density and pressure inside the upper ionosphere model. Simulation with  $T_{sw} = 1.8 \cdot 10^5$  K,  $n = 20$  cm $^{-3}$ ,  $|v| = 350$  km/s, and  $|B|_{IMF} = 0$ .

the profiles of the density and pressure inside the upper ionosphere model for the simulation with  $T_{sw} = 1.8 \cdot 10^5$  K,  $n = 20$  cm $^{-3}$ ,  $|v| = 350$  km/s, and  $|B|_{IMF} = 0$ .

The initial model conditions for the plasma density and pressure are defined to have a smooth transition between the upper ionosphere and the simulation domains. During the simulation, the pressure and density gradients increased because the density and pressure profiles were fixed inside the inner ionosphere, but evolved freely in the simulation domain. The answer of the system during the early stages of the simulation is to compensate for the gradients feeding plasma toward the simulation domain, generating an outward plasma flux that saturates when the inner magnetosphere reaches the steady state. Henceforth, the plasma flows are dominated by the balance between the SW injection inside the inner magnetosphere and the plasma streams toward the planet surface.

The numerical model we used to study space weather configurations with low SW dynamic pressure,  $P_d \leq 1$  nPa, was modified with respect to high  $P_d$  simulations. The inner boundary was located at  $R_{in} = 3R_E$  and the upper ionosphere domain between  $3.0 - 3.5R_E$ . The reason for this modification was that we wished to avoid an overestimation of the magnetosphere thermal pressure in low  $P_d$  simulations. This can be caused by the plasma Alfvén velocity that is imposed in the upper ionosphere, which is required to control the simulation time step and may lead to an artificial enhancement of the plasma fluxes toward the simulation domain. This numerical issue was avoided by displacing the inner boundary of the model outward. This reduced the fluxes and minimized the overestimation of the magnetosphere thermal pressure. For high  $P_d$  simulations, the effect of outward fluxes is negligible in the pressure balance.

The model prediction for quite space weather conditions was compared with the analysis of Samsonov et al. (2016) by performing a simulation using the same parameters as in the original benchmark study:  $n = 5$  cm $^{-3}$ ,  $V_x = -400$  km/s,  $T = 2 \cdot 10^5$  K,  $B_y = -B_x = 3.5$  nT, and  $B_z = 0$  nT. The location of the magnetopause is  $R_x/R_E = 10.7$ ,  $R_y/R_E = 16.8$ ,  $R_{-y}/R_E = 16.6$ , and  $R_z/R_E = 14.9$ . The model prediction and the benchmark study agree reasonably well. Figure A.2 shows the electric field in the simulation domain. The local maximum of the electric field is also consistent with the simulations in Samsonov et al. (2016) near the BS (fig 1). There is a secondary local maximum of the electric field module near the lower boundary of the simulation domain that is caused by the conditions imposed in the upper

ionosphere. The module of the electric field predicted inside the magnetosphere is similar to Cluster spacecraft observations during the magnetopause crossing on 30/02/2002 (De Keyser et al. 2005). The electric field measured in the current sheet and magnetosheath is one order of magnitude higher than the simulations because the IMF module is 10 times larger during the Cluster magnetopause crossing. When the simulation was performed using a southward IMF with  $|B| = 50$  nT and  $P_d = 5$  nPa, similar to the space weather conditions during Cluster magnetopause crossing, the predicted electric field is 15 – 30 mV/m in the current sheet and magnetosheath region. This is similar to Cluster spacecraft observations.

**Fig. A.2.** Electric field module in the simulation domain for the benchmark case in Samsonov et al. (2016) in (a) the XZ plane and (b) in the YZ plane.

In addition, another two simulations were performed using the same SW parameters, but for northward and southward IMF orientations with  $|B_{z1}| = 3$  nT, identifying the displacement of the magnetopause location defined as  $\Delta R/R_E = \text{northward}(R)/R_E - \text{southward}(R)/R_E$ :  $\Delta R_x/R_E = 0.2$ ,  $\Delta R_y/R_E = 0.1$  and  $\Delta R_z/R_E = -1.0$ . Again, there is a reasonable agreement.

Next, the model was compared with the Carrington-like event analyzed by Ridley et al. (2006), who identified a magnetopause standoff distance of  $R/R_E = 2$  (equal to the lower boundary of the simulation domain) for the parameters  $n = 750$  cm<sup>-3</sup>,  $V_x = -1600$  km/s ( $P_d = 1600$  nPa),  $T = 3.5 \cdot 10^7$  K,  $B_x = 150$  nT,  $B_y = 170$  nT, and  $B_z = 200$  nT. Our model cannot be used to simulate space weather conditions leading to a magnetopause standoff distance smaller  $R/R_E = 2.5$ , although the extrapolation of the model results predicts  $R/R_E \approx 1.22$  if  $P_d = 1600$  nPa and  $B_z = 200$  nT (pure southward IMF orientation).

The electric field in the upper ionosphere domain remains almost unchanged during the simulation because the density profile was fixed. Figure A.3 panel a shows the radial electric field inside the upper ionosphere (North hemisphere at  $R/R_E = 3.1$ ) for the Samsonov et al. (2016) benchmark case, indicating a reasonable order-of-magnitude agreement with respect to other models and satellite measurements (Shume et al. 2009; Alken & Maus 2010; Watanabe et al. 2014). Panel b indicates the FAC intensity and orientation, values in the range of the observations and modeling data (from nA/m<sup>2</sup> to several  $\mu$ A/m<sup>2</sup> regarding the space weather conditions) Weimer (2001); Waters et al. (2001); Ritter et al. (2013); Bunescu et al. (2019); Zhang et al. (2020).

**Fig. A.3.** (a) Radial electric field and (b) FAC intensity in the North Hemisphere at  $R/R_E = 3.1$  for the Samsonov et al. (2016) benchmark case. The colored isocontours indicate different FAC intensities and inward and outward (green and pink) orientations.

## Appendix B: Magnetic field line mapping

The magnetic field lines of the simulations were mapped with respect to the magnetic field of an unperturbed dipole. To this end, a simulation without the driving effect of the SW and IMF was performed in which we decreased the inner boundary of the simulation domain to  $R/R_E = 1$ . Figure B.1 shows the mapping of the magnetic field lines for simulations during regular and extreme space weather conditions with the magnetic field of an unperturbed dipole.

The mapping shows that even for simulations with a high dynamic pressure (panel b) and  $|B|_{IMF}$  (panel c), the magnetic field lines follows the unperturbed dipole magnetic field lines inside the computational domain of the upper ionosphere, between  $R/R_E = 2$  to 2.5, indicated in the figures by the dashed and dotted white line. Consequently, the extrapolations of the OCB line and plasma flows toward the Earth surface are reasonably accurate.

## Appendix C: Magnetotail and OCB line latitude on the nightside

The simulation outer boundary is located at  $R/R_E = 30$ , although the magnetotail extension can exceed  $R/R_E = 30$ , thus this magnetosphere structure is only partially reproduced by the model. Consequently, the last close magnetic field line cannot be accurately identified on the Earth NS, and this also holds for the latitude of the OCB line. This is the case for the simulations with  $P_d \geq 85$  nPa and  $|B|_{IMF} \leq 10$  nT. Therefore the analysis of the OCB line latitude on the NS was not performed for these configurations. Nevertheless, the outer boundary conditions might affect the magnetotail topology when the simulation reaches steady state. Figure C.1 compares the magnetotail structure in simulations for the same space weather conditions, but increasing the outer boundaries from  $R/R_E = 30$  to 100.

The simulations with the outer boundary at  $R/R_E = 30$  and 100 agree well regarding the Earth magnetic field on the DS and NS, indicating that the outer boundary conditions have a negligible effect on the computational domain. Consequently, the location of the last close magnetic field lines on the NS is similar, leading to values of the OCB line latitude inside the uncertainty of the model resolution.

**Fig. B.1.** 3D view of the magnetic field line mapping between an unperturbed dipole and simulations with (a) no IMF and  $P_d = 2$  nPa, (b) Sun-Earth IMF  $|B|_{IMF} = 10$  nT and  $P_d = 105$  nPa, and (c) Sun-Earth IMF  $|B|_{IMF} = 100$  nT and  $P_d = 2$  nPa. The dashed white line indicates the inner boundary of the simulation domain ( $R/R_E = 2$ ), and the dotted white line shows the upper boundary of the ionosphere model ( $R/R_E = 2.5$ ). The red lines show the magnetic field lines in the simulation with only the dipole magnetic field and the blue lines the magnetic field lines in the simulation with dipole + IMF magnetic fields.

## Appendix D: CME list

Table D.1 shows the SW density, temperature, radial velocity, dynamic pressure, IMF components, and module as well as the data source for the CME subsample.

The simulation inputs were obtained from OMNIWeb (OMN 2020), ACE SWICS (ACE 2020), and DSCOVR (DSC 2020) after the front of the ICME impacted the Earth. OMNIWeb pro-

**Fig. C.1.** Polar plot of the magnetic field lines in simulations with the outer boundary at  $R/R_E = 30$  (red line) and 100 (green line) for the 27/05/2017 ICME. The gray sphere indicates the outer boundary of the simulation with at  $R/R_E = 30$ .

vides high-resolution OMNI (HRO) data based on the Global Geospace Science (GGS) Wind satellite (Ogilvie & Desch 1997), ACE SWICS data from the Advanced Composition Explorer (ACE) spacecraft (Stone et al. 1998), and DSCOVR data from the Deep Space Climate Observatory (Burt & Smith 2012). The strong CME impacting the Earth on 29/10/2003 is not included in the list because no data for the SW density and temperature nor for the IMF module and intensity are available.

Figures D.1 and D.2 show two examples of the space weather condition obtained from OMNIWeb. We used them as input for the simulations for the ICMEs on 15/05/1997 and 31/03/2001, respectively.

**Fig. D.1.** OMNIWeb data during the 15/05/1997 ICME. (a)  $|B|$  (nT), (b)  $B_x$  (nT), (c)  $B_y$  (nT), (d)  $B_z$  (nT), (e)  $|v|$  (km/s), (f)  $v_r$  (km/s), (g)  $n$  ( $\text{cm}^{-3}$ ), and (h)  $T$  ( $10^4$  K). The solid red line indicates the time frame we selected as the simulation input.

Date (dd/mm/yyyy) (hh:hh)	$n$ ( $\text{cm}^{-3}$ )	$T$ ( $10^3$ K)	$V_r$ (km/s)	$P_d$ (nPa)	$B_x$ (nT)	$B_y$ (nT)	$B_z$ (nT)	$ B _{sw}$ (nT)	Source	$K_p$

**Table D.1.** SW and IMF parameters of the CME selection between 1997 – 2020. Date (first column), SW density (second column), SW temperature (third column), SW radial velocity (fourth column), SW dynamic pressure (fifth column), IMF component along the Sun–Earth direction (sixth column), IMF component along the magnetic axis direction (seventh column), IMF component along the ecliptic direction (eighth column), IMF module (ninth column), data source (tenth column), and measured  $K_p$  index (eleventh column).

**Fig. D.2.** OMNIWeb data during the 31/03/2001 ICME. (a)  $|B|$  (nT), (b)  $B_x$  (nT), (c)  $B_y$  (nT), (d)  $B_z$  (nT), (e)  $|v|$  (km/s), (f)  $v_r$  (km/s), (g)  $n$  ( $\text{cm}^{-3}$ ), and (h)  $T$  ( $10^4$  K). The solid red line indicates the time frame we selected as the simulation input.

## Appendix E: Acronym list

### Appendix F: Parameter list for the simulations

The SW and IMF parameters in the simulations included in figures 6, 10, 11, 12, 13, 14, and 15 are (for Sun–Earth, Earth–Sun, northward, southward and ecliptic ctr-clockwise IMF orientations) listed below.

The SW and IMF parameters in the simulations included in figures 8 and 9, for which we fixed the SW velocity and temperature are (for the Sun–Earth IMF orientation) listed below

Acronym	Meaning
IMF	Interplanetary Magnetic Field
SW	Solar Wind
MHD	Magneto Hydro Dynamic
CME	Coronary Mass Ejection
ICME	Interplanetary Coronal Mass Ejection
$Dst$	Disturbance Storm Time Index
BS	Bow Shock
DS	Dayside
NS	Nightside
OCB	Open-Close Boundary

**Table E.1.** Acronym list.

The SW and IMF parameters in the simulations included in the figures 8 and 9, for which we fixed the SW density and temperature are (for the Sun–Earth IMF orientation) listed below.

The SW and IMF parameters in the simulations included in figure 9 fixing the SW density and velocity are (for the Sun–Earth IMF orientation) listed below.

The SW and IMF parameters in the simulations included in the figures 16 and 17, for which we fixed the SW density and temperature are (for Earth–Sun, northward, southward, and ecliptic ctr-clockwise IMF orientations) listed below.

$n$ (cm <sup>-3</sup> )	$T$ (10 <sup>3</sup> K)	$V_r$ (km/s)	$P_d$ (nPa)	$ B _{sw}$ (nT)
