ABSTRACT

Context. This paper relates to low-mass star formation in globules, and the interaction of newly-formed stars with their environment. We follow up on the results of our earlier observations of this globule.

Aims. Our aim is to study the gas- and dust environment of the young stellar object (YSO) in globule CB88 230, the large-scale molecular outflow triggered by the jet driven by the YSO, and their interaction.

Methods. We carried out submillimetre continuum and multi-line molecular observations with several single-dish facilities, mapping the core of the globule and the large-scale outflow associated with the YSO.

Results. Dust continuum and molecular line maps (of ^{12}CO , C^{18}O , CS, CH_3OH) show a flattened (axes ratio 1.5–1.7), asymmetric core with a full width at half maximum (FWHM)-diameter of 0.16–0.21 pc. Line profiles of ^{12}CO , $^{13}\text{CO}(2-1, 3-2)$, and $\text{CS}(2-1)$ show self-absorption near the YSO; the absorption dip is at a slightly ($\sim 0.3 \text{ km s}^{-1}$) redder velocity than that of the quiescent gas, possibly indicating infall of cooler envelope gas. The mass of the core, determined from $\text{C}^{18}\text{O}(1-0)$ observations, is about $8 M_{\odot}$, while the virial mass is in the range $5-8 M_{\odot}$, depending on the assumed density distribution. We detect a slight velocity gradient ($\sim 0.98 \text{ km s}^{-1} \text{ pc}^{-1}$), though rotational energy is negligible with respect to gravitational and turbulent energy of the core. A fit to the spectral energy distribution of the core gives a dust temperature $T_d \approx 18 \text{ K}$ and a gas mass of ca. $2 M_{\odot}$ (assuming a gas-to-dust ratio of 100). More careful modelling of the sub-mm emission (not dominated by the relatively hot central regions) yields $M \approx 8 M_{\odot}$. From the molecular line observations we derive gas temperatures of 10–20 K. A Bayesian analysis of the emission of selected molecules observed towards the YSO, yields $T_{\text{kin}} \approx 21.4 \text{ K}$ (68% credibility interval 14.5–35.5 K) and volume density $n(\text{H}_2) \approx 4.6 \times 10^5 \text{ cm}^{-3}$ ($8.3 \times 10^4 - 9.1 \times 10^5 \text{ cm}^{-3}$). We have mapped the well-collimated large-scale outflow in $^{12}\text{CO}(3-2)$. The outflow has a dynamical age of a few 10^4 yr, and contains little mass (a few $10^{-2} M_{\odot}$). A misalignment between the axis of this large-scale outflow and that of the hot jet close to the YSO indicates that the outflow direction may be changing with time.

Key words. stars: formation – stars: pre-main sequence – ISM: clouds – ISM: jets and outflows – ISM: individual objects: CB88-230

1. Introduction

Studies of the molecular environment in star-forming regions are often complicated by the presence of multiple emission line components at different velocities and by young stellar objects (YSOs) in different evolutionary stages stirring up the molecular cloud. This complication can be avoided by selecting a small cloud, such as a Bok globule, which is cold ($\sim 10-20 \text{ K}$) and relatively isolated, and in which only one or at most a few low-mass stars are being formed at the same time. Such small clouds consist of a dense core which can be starless, or host an embedded protostar or a slightly more evolved object, surrounded by a lower-density envelope.

A phenomenon associated with the early stages of the formation of stars of all masses are bipolar outflows, which in one scenario are the result of ambient molecular gas being swept up by fast, collimated winds from a YSO. Closest to the YSO one finds the fast, hot, jet-like component that can be detected through H_2 ro-vibrational lines at $T_{\text{ex}} \sim 2000 \text{ K}$ and by [FeII]-line emission. Further from the central object the flow cools down and where it hits the gas of the ambient cloud in which the star formation takes place, one may find molecular species with enhanced abundances as a consequence of being produced in a shock-driven chemistry (e.g. SiO, but also SO and CH_3OH ;

Bachiller 1996 and references therein). The cloud material is entrained by the jet component through turbulent flows or bow-shocks, and is driven away from the YSO to larger distances. This swept-up cloud material is the coolest ($T_{\text{ex}} \approx 10-20 \text{ K}$; Bachiller 1996) component and is often easily observable through the emission of the lower-J transitions of CO. Another mechanism by which cloud material can be entrained is by wide-angle winds, launched from the accretion disk around the YSO. This wind blows into the ambient gas and forms a swept-up shell of matter, usually leading to a less collimated flow.

In a previous paper (Massi et al. 2004) we described our search for the jet-component in the near-infrared (NIR) through narrow-band H_2 ($2.122 \mu\text{m}$) and [FeII] ($1.644 \mu\text{m}$) filters in four star-forming (Bok) globules. In two of the globules H_2 and [FeII] emission remained after careful subtraction of the underlying continuum (Massi et al. (2004): CB3 and CB230 (LDN1177)). The latter is the subject of the present paper¹.

CB230 is a $3/4 \times 2/2$ (Clemens & Barvainis 1988) globule at high galactic latitude ($13^{\circ}.16$), probably associated with the reflection nebula Sh2-136 (a.k.a. vdB 141). The star illuminating the reflection nebula (BD+67 1300) has a parallax of

¹ The official nomenclature for these objects is CB88 3 and CB88 230; for convenience we will use CB3 and CB230.

Fig. 1. Optical image (LRGB filters) of CB230 and surroundings. Approximate size $19'.5 \times 13'$. East is left, north is up. The bright patch below the centre with the veiled star BD+67 1300, is the reflection nebula Sh2-136/vdB 141. CB230 is the more opaque structure in the eastern part of the cloud, in which the cone of scattered light, associated with the outflow studied in this paper (Sect. 3.4), is clearly visible. Image credit: Adam Block, Mount Lemon Sky Center, University of Arizona, USA. Used with permission.

2.95 ± 0.35 mas (Gaia Collaboration 2016), meaning a distance of $339(+46, -36)$ pc². We also adopted this as the distance to CB230; it is in agreement with the 300 pc used by Tobin et al. (2013), and the 293 ± 54 pc lower limit derived by Das et al. (2015). Embedded in CB230 is a YSO near the position of the IRAS source IRAS 21169+6804 ($L_{\text{fir}} \sim 6.5\text{--}6.8 L_{\odot}$; Young et al. 2003; Launhardt & Henning 1997; scaled to $d = 339$ pc). Yun & Clemens (1994a) detected a bipolar outflow in low-resolution ($48''$) $^{12}\text{CO}(1\text{--}0)$ observations. Their NIR observations at 1.25 and $2.2 \mu\text{m}$ (Yun & Clemens 1994b) show a $16''$ conical nebula that is open to the north. The IRAS source is at the apex of this nebula at the NIR peak. It is also detected in (sub)millimetre continuum emission (Launhardt & Henning 1997; Huard et al. 1999; Young et al. 2003; Launhardt et al. 2013). Figure 1 shows an optical image of LDN1177, the reflection nebula and the globule CB230. At the location of the embedded YSO a cone of scattered light is clearly visible.

The jet detected by Massi et al. (2004) in [FeII], originating from the YSO in CB230, is defined by two knots superimposed on a fainter, elongated emission feature (Fig. 5 in Massi et al. 2004). This jet is also traced by H_2 emission, which is weaker and slightly less narrow than that of [FeII]. The presence of strong [FeII] and weaker H_2 emission suggests the presence of

fast, dissociative J-shocks. This is confirmed by the NIR spectra analysed by Massi et al. (2008). These authors also identify the YSO (CB230-A) as a Class 0/I object, confirming the classification by Froebrich (2005). A close companion, $\sim 0'.3$ northeast of CB230-A was found by Tobin et al. (2013); it appeared to be resolved in their high-resolution Very Large Array (VLA) observations at 7.3 mm; its diameter of ~ 45 AU is interpreted by these authors as being indicative of a circumstellar disk. Considering also the embedded binary object (CB230-B1,2) found at about $9''$ east³ of CB230-A by Massi et al. (2004), this globule may contain a quadruple system. In the present paper we present molecular line- and submillimetre continuum data of the outflow and of the core from which it originates and in which the YSO (CB230A) is embedded.

2. Observations and data reduction

The various observations we carried out and which are described in this section, were not all centred on the same coordinates (though within $7''.4$). To facilitate comparison, unless stated otherwise, all offsets in this paper, including the figures, are relative to the YSO position (2MASS-coordinates). In Table 1 we give the positions of the point source detected at the apex of the nebula, as reported by different authors, and the IRAS-position, and the offsets with respect to the 2MASS-position.

³ In Massi et al. (2004) it erroneously says “west”.

² Gaia Collaboration (2018) lists the parallax of this star as 2.9075 ± 0.0208 mas, that is a distance of $343.94(+2.48, -2.44)$ pc, a difference of only $\sim 1.5\%$ with the value adopted here.

Table 1. Central coordinates used in the observations, and reference coordinates.

2.1. Millimetre lines

Details of the line observations (frequencies, resolution, rms, etc.) can be found in Table 2. All rms-temperatures are in units of T_A^* , unless specified otherwise.

2.1.1. James Clerk Maxwell Telescope

On 10 September, 2003 we used RxB3 at the 15-m *James Clerk Maxwell* Telescope (JCMT) on Mauna Kea (Hawaii) to observe $^{12}\text{CO}(3-2)$ towards CB230 in the raster (on-the-fly) observing mode. The map covers a $90'' \times 230''$ region. The JCMT beam-size at 345 GHz is $\sim 14''$; observations were made on an $8''$ raster, using the DAS autocorrelator spectrometer. An off-position was used at offset $-600''$ in Declination from the map's centre position. The low-resolution map of the outflow by [Yun & Clemens \(1994a\)](#) was used to select the area to be observed. We searched for emission of $\text{SiO}(5-4)$ (which would trace shock emission) at 5 locations in the outflow.

In the period 26–29 September, and on 4 October 2004 we observed $^{13}\text{CO}(3-2)$ in a $50'' \times 80''$ region towards the central region of the outflow seen in the $^{12}\text{CO}(3-2)$ map. The raster spacing was again $8''$.

In addition, we observed $\text{C}^{18}\text{O}(2-1)$ at 15 positions along the axis of the outflow. At 4 positions in the outflow we made deeper observations in the $J=2-1$ and $J=3-2$ transitions of ^{12}CO , ^{13}CO , and C^{18}O , in order to study the line profiles in more detail. Likewise, we searched for $\text{SO}(6_5-5_4)$ emission (219.9 GHz) at 3 of these positions.

In addition we looked for emission of $\text{CS}(5-4)$, $\text{HCN}(3-2)$, $\text{HCO}^+(3-2)$ and $(4-3)$, $\text{DCO}^+(3-2)$, $\text{CH}_3\text{OH}(5_k-4_k)$, and $\text{H}_2\text{CO}(3_{03}-2_{02})$, $(3_{22}-2_{21})$, and $(3_{12}-2_{11})$ at the position of the embedded YSO, which coincides with the centre of the outflow and the peak of the sub-mm continuum observations.

Main beam efficiencies in the 230 and 345 GHz bands were 0.68 and 0.63, respectively.

For line-checks and calibration we observed G34.3, W75N, and NGC7538IRS1. The data were reduced with the program CLASS, which is part of the Gildas-software package developed by the Observatoire de Grenoble and the Institut de Radioastronomie Millimétrique (IRAM).

2.1.2. IRAM 30-m

CB230 was observed simultaneously in $^{12}\text{CO}(2-1)$, $^{13}\text{CO}(2-1)$, $\text{CS}(2-1)$, and $\text{SO}(3_2-2_1)$ with the IRAM 30-m telescope at

Pico Veleta (Granada, Spain) in the period August 7–10, 2004. The observations of an area of $60'' \times 104''$ containing the red- and the strongest part of the blue outflow found with the JCMT in $^{12}\text{CO}(3-2)$, were made in the on-the-fly (OTF) observing mode, scanning along mutually orthogonal strips in right ascension and declination. The strips are separated by $4''$. Subsequently, the map was gridded on a $4'' \times 4''$ raster. The reference position for these observations was taken at offset $(0'', -600'')$ with respect to the map's centre position.

In addition $\text{SiO}(2-1)$, $\text{H}^{13}\text{CO}^+(1-0)$, $\text{CH}_3\text{OH}(2_k-1_k)$ and $(5-4)$, and $\text{H}_2\text{S}(2_{20}-2_{11})$ were observed on a 2×5 -grid, with spacing $16''$, centred on $(-9'', -2'')$ with respect to the YSO-position, using position-switching against the same reference position as above. All spectra were reduced with the Grenoble CLASS software. Low-order polynomial baselines were subtracted.

2.1.3. Onsala

Between May 26 and 31, 2005, we used the 20-m telescope of the Onsala Space Observatory (Sweden) to observe emission of $\text{C}^{18}\text{O}(1-0)$, $\text{CS}(2-1)$ and $\text{CH}_3\text{OH}(2_k-1_k)$ towards a $4' \times 3'$ region in CB230. The observations were carried out in position-switching mode, using a nearby emission-free position as reference. Pointing was regularly checked by observing the $\text{SiO}(1-0, \nu=1)$ maser emission from TX Cam and R Cas, and was found to be accurate to within $3''$. Observations were carried out using an SIS-mixer and a low-resolution hybrid correlator, which gave a total velocity coverage of about 200 km s^{-1} . Beam efficiencies at 97 and 110 GHz were approximately 0.56 and 0.45, respectively (e.g. [Johansson 2002](#)). All spectra were reduced with the Grenoble CLASS software.

2.2. Submillimetre continuum

On September 10, 2003 we simultaneously observed the $450 \mu\text{m}$ and $850 \mu\text{m}$ emission towards CB230 with the Submillimetre Common-User Bolometer Array (SCUBA; [Holland et al. 1999](#)) at the JCMT. A standard 64-point jiggle map was made, which covers an area $2/3$ in diameter; hence the observations were limited to the region immediately around the IRAS source. The rms values in the CB230 maps were $150 \text{ mJy beam}^{-1}$ (at $450 \mu\text{m}$) and 10 mJy beam^{-1} (at $850 \mu\text{m}$), respectively.

Since then, SCUBA-2 observations of superior quality have become available, and we have decided to use these archival data instead.

On June 27–30, 2012 CB230 was observed simultaneously at $450 \mu\text{m}$ and $850 \mu\text{m}$ with the Submillimetre Common-User Bolometer Array 2 (SCUBA-2; [Holland et al. 2013](#)) at the JCMT. In total six constant velocity (CV) Daisy observations were made on the four nights and retrieved by us from the archive. The 225 GHz optical depth was 0.04–0.05 on all nights, except during the second Daisy on June 28 (due to bad weather) and those data were not used.

CV Daisy observations are designed for small and compact ($\lesssim 3'$) sources, although there is significant exposure time in the map out to $12'$. The SCUBA-2 data were reduced with the dynamic iterative map-maker ([Chapin et al. 2013](#)) and an isolated source configuration file. Calibration was performed by using water vapour monitor data at 186 GHz, scaled to give the optical depth at 225 GHz, and average ratios of $\tau(450 \mu\text{m})$ and $\tau(850 \mu\text{m})$ to $\tau(225 \text{ GHz})$. The final transition from instrumental parameters to Jy beam^{-1} (the flux conversion factor) was derived from calibration observations of Uranus and CRL2688 made on the same night and reduced with the same pixel size

Table 2. Details of the molecular line measurements.

Notes. ^(†)Frequencies as used at the telescope. (1) Refers to the deep observations at selected positions. (2) Refers to the spectra in the map. (3) Refers to the spectra taken along the outflow axis. (4) Resolution and rms quoted for resampled spectra, with the resolution cited in Cols. 6 and 7. OTF refers to maps made in On-The-Fly-mode.

as the science observations (see [Dempsey et al. 2013](#)). The half-power beamwidths at 450 μ m and 850 μ m are about 7.9'' and 13'', respectively. The rms values in the CB230 maps are 50 mJy beam⁻¹ (at 450 μ m) and 4 mJy beam⁻¹ (at 850 μ m), respectively.

Because the CO(3–2) line is within the bandpass of the SCUBA-2 850 μ m filter, these data have been corrected for this contamination which can be significant, in particular at the location of strong outflow sources. We followed the procedure

outlined by [Parsons et al. \(2018\)](#), using the CO(3–2) integrated intensity ($\int T_{\text{mb}} dv$) map as a negative fake map, to be combined with the SCUBA-2 data in the map maker (see also [Drabek et al. 2012](#)). The derived CO-contamination was typically less than 5%.

2.3. Radio lines

On April 14, 2005 we searched for H₂O(6₁₆–5₂₃) (22.2350798 GHz) maser emission with the Medicina 32-m

telescope⁴ at the location of the YSO in the core of CB230. In December 2004 we observed CH₃OH at four frequencies (23.35–24.96 GHz).

We used a bandwidth of 10 MHz and 1024 channels, resulting in a resolution of 9.76 kHz; the HPBW at 22 GHz was ~ 1.7 . With our setup only the LHC polarisation is registered. The pointing accuracy was always better than $25''$; the rms residuals from the pointing model were of the order of $8''$ – $10''$. Observations were taken in total power mode, with both ON and OFF scans of 5 min duration. The OFF position was taken 1.25 E of the source position to rescan the same path as the ON scan. Six ON,OFF pairs were taken at this position.

Calibration was done by observing the continuum source DR 21 (for which we assume a flux density of 16.4 Jy after scaling the value of 17.04 Jy given by Ott et al. (1994) for the ratio of the source size to the Medicina beam) at a range of elevations during the day. The typical calibration uncertainty is approximately 20%. For further details on Medicina observations, see Felli et al. (2007).

No detections were made in any of these observations.

3. Results

3.1. Core: dust continuum

In Figs. 2 and 3 we show the SCUBA-2 maps of the dust continuum. Also shown are the intensity profiles along two strips (as indicated in the images).

The continuum emission at $850\mu\text{m}$ peaks at offset $0'',0''$ and thus (see Table 1) coincides with the YSO. At $450\mu\text{m}$ the peak lies approximately at offset $0'',+2''$; in agreement, considering the pixel sizes ($2''$ at $450\mu\text{m}$, $4''$ at $850\mu\text{m}$) The emission is asymmetric (more extended to the west) and elongated, with an aspect ratio (extent in RA/extent in Dec) of about 1.5, confirming what is seen in the SCUBA data from Launhardt et al. (2010). The asymmetry is seen also in our own SCUBA observations, but not in the much less sensitive SCUBA images from Huard et al. (1999) and Young et al. 2003. The westward extension of the $850\mu\text{m}$ emission traces quite closely the essentially one-sided extinction contours at $8\mu\text{m}$ (Tobin et al. 2010). Tobin et al. (2010) argue that these asymmetries are more likely to be due to the initial cloud structure and/or the dynamics of the star formation process, rather than to sculpting by the outflow.

Figure 4 shows the distribution of $350\mu\text{m}$ emission observed with the *Herschel* satellite (Launhardt et al. 2013) in the area observed in different molecular species with the Onsala telescope (see Sect. 3.2.3). The middle-sized white box represents the area in the SCUBA-2 maps in Figs. 2 and 3. The $350\mu\text{m}$ emission follows the SCUBA-2 emission except that the western extension in the SCUBA-2 map is a separate peak in the *Herschel* map.

Flux densities at the two SCUBA-2 wavelengths were calculated by integrating all emission above the 3σ -contour, and sizes of the dust-emission core were determined from the half-peak value contour as well as from the 3σ level, and were corrected for beam size. The results are collected in Table 3.

Figure 5 shows the spectral energy distribution (SED) of CB230. We have plotted our two sub-millimetre data points, in addition to the *Herschel* flux densities at 70, 100, 160, 250, 350 and $500\mu\text{m}$, extracted from Fig. 4 in Launhardt et al. (2013). We also included a data point at 1.3 mm (Launhardt et al. 2010). We have made a grey-body fit to these data points; the fit is shown

Fig. 2. SCUBA-2 map of the dust continuum emission at $850\mu\text{m}$ (corrected for CO(3–2) emission; *left panel*), and profiles along cuts A and B. The $850\mu\text{m}$ peak is at $(0'',0'')$. Contours (lowest(step)highest) are 12, 20(20)80(80)400(160)720 mJy beam^{-1} . The rms noise is 4 mJy beam^{-1} .

Fig. 3. SCUBA-2 map of the dust continuum emission at $450\mu\text{m}$ (*left panel*), and profiles along cuts A and B. The $450\mu\text{m}$ peak is at $(0'',2'')$. Contours (lowest(step)highest) are 150, 300, 500(500)3500 mJy beam^{-1} . The rms noise is 50 mJy beam^{-1} .

Fig. 4. *Herschel* $350\mu\text{m}$ map of the area in CB230 mapped with the Onsala telescope (Sect. 3.2.3). The larger and smaller white box indicate the area of the SCUBA-2 maps (Sect. 3.1) and the IRAM maps (Sect. 3.2.4), respectively. Contour values are 35, 50, 75, 100, 150, 200, 300, 400 MJy sr^{-1} . Offsets are relative to the 2MASS position of the YSO (see Table 1).

as the red curve. The SED-fit shown in Fig. 5 was obtained by assuming a dust opacity $k_\nu = k_{344.6}(\nu[\text{GHz}]/344.6)^\beta$, with $k_{344.6} = 1.85\text{ cm}^2\text{ g}^{-1}$ the opacity at $870\mu\text{m}$ (derived from the numbers given in Ossenkopf & Henning 1994) and $\beta = 1.8$, and

Table 3. Core parameters derived from the continuum measurements.

	$\phi_{\text{hp}}^{(a)}$ pc	$\phi_{3\sigma}^{(b)}$ pc	$S^{(c)}$ Jy	F_{peak} Jy beam $^{-1}$	σ
450 μm	0.016	0.087	16.99	3.53	0.050
850 μm	0.023	0.16	3.04	0.76	0.004

Notes. ^(a)Equivalent diameter at half-peak level, corrected for beam size ($d = 339$ pc). ^(b)Equivalent diameter at 3σ level, corrected for beam size ($d = 339$ pc). ^(c)Integrated flux density above the 3σ -level.

Fig. 5. Spectral energy distribution (SED) of CB230. The data shown are the SCUBA-2 measurements at 450 and 850 μm (corrected for CO(3–2)-emission), the integrated flux at 1.3 mm (Launhardt et al. 2010), and the *Herschel* data points at 70, 100, 160, 250, 350 and 500 μm (extracted from Fig. 4 in Launhardt et al. 2013). The fit to the data (red) was obtained by assuming a dust optical depth at 870 μm of $1.85 \text{ cm}^2 \text{ g}^{-1}$, and a dust absorption coefficient β of 1.8. The yellow and green bands indicate the uncertainty in the modelled fluxes for the 68 and 95% credibility intervals of T_{dust} and M_{dust} , assuming that the uncertainty on the measured fluxes is 20%.

a gas-to-dust ratio of 100. This results in $T_{\text{dust}} = 18.2 \pm 2.0$ K and a total mass derived from the continuum emission $M_{\text{cont}} = 1.7 \pm 1.0 M_{\odot}$ at the 95% credibility level. This is virtually identical to the $2.0 M_{\odot}$ (when scaled to the same gas-to-dust ratio and distance as used here) derived by Launhardt et al. (2013) from a SED-fit to the integrated fluxes in the core region.

To perform a more sophisticated analysis of the dust continuum data, and get a more realistic value of the total (gas+dust) mass and investigate the volume density profile of the core, we used RATRAN⁵ (Hogerheijde & van der Tak 2000). To reproduce the observed flux density distribution of the dust continuum emission we constructed a grid of one-dimensional models of the core. We assumed a gas-to-dust ratio of 100, and a central heating source ($L_{\text{bol}} = 6.8 L_{\odot}$) that gives rise to a temperature profile $\propto r^{-0.4}$, where r is the distance from the YSO-position, and a density distribution in the core that is $\propto r^p$, up to a threshold of $2 \times 10^6 \text{ cm}^{-3}$, above which it is assumed to be flat. We varied p between -1.7 and -1.5 in steps of -0.025 , and the total mass of the core between $7.2 M_{\odot}$ and $8.8 M_{\odot}$, in steps of $0.05 M_{\odot}$. We focussed on this narrow range in mass after a preliminary, coarser run of models with a larger mass range (0.5 – $20 M_{\odot}$). The model was then smoothed with a Gaussian kernel to the angular resolution appropriate for each of the SCUBA2 wavelengths, and compared to the observations with a Bayesian approach. Figure 6 summarises the results of this modelling effort. In panel a we show the observed fluxes at 850 μm in red and at 450 μm in blue, with the best-fit model indicated by the solid lines. The

Fig. 6. *Top panel:* flux density (Jy beam^{-1}) as a function of distance (in arcsec) from the YSO-position for 450 (blue) and 850 μm (red). The lines are the best fit model obtained with RATRAN (see text for details). *Bottom panel:* the joint probability distribution of total (gas + dust) mass and density profile.

data points represent the flux density for each pixel, and the radial distance is computed from the continuum peak position. The uncertainty of a single point is obtained by summing in quadrature a calibration uncertainty of 20%, the image noise and a fixed term given by the maximum spread between the pixels at similar distances, to mitigate the influence of the elongated structure of the core. Panel b shows the joint probability density of p and mass, as well as their marginalised probability densities in the bottom and right subplots. The best-fit values correspond to $p = -1.79 \pm 0.15$ and $M = 8.0 \pm 0.5 M_{\odot}$.

This mass is the same as the one derived from our C^{18}O -data (see Sect. 3.2.3), but more than four times higher than the $1.7 M_{\odot}$ that was derived from the SED-fit. A possible explanation for this discrepancy might be that the fluxes used in the SED-fit are dominated by the relatively hot central region, so that the temperature derived from the SED-fit is overestimated, and the mass underestimated (more representative values for the overall core-temperature are several degrees lower, see Sect. 3.2; for example, for $T_{\text{dust}} = 13$ K the integrated flux at 850 μm above 3σ implies a total mass $M \sim 3.6 M_{\odot}$). In addition, we made the assumption of symmetry in the model calculation of the dust mass, whereas it is clear from Fig. 2 that the emission is extended more to the west. We have also assumed that the dust core has the same extent along the line-of-sight as it has in the plane of the sky. These assumptions may lead to an overestimate of the dust- (and thus gas-) mass. In fact, recently Sadavoy et al. (2018) performed a pixel-by-pixel SED-fit to, among others, CB230, using newly zero-point-corrected *Herschel* data, and find $T_{\text{dust}} \approx 17$ – 19 K at the YSO-location, but 15 ± 1 K around it, and even 13 – 14 K just to the west of it (their Fig. 17f). For the core-region these T_{dust} -values are very similar to those found in an earlier dust temperature map by Launhardt et al. (2013).

⁵ www.sron.rug.nl/~vdtak/ratran

The opacity law that we used in both the RATRAN-modelling and the SED-fit, is that of [Ossenkopf & Henning 1994](#), for grains with thin ice mantles and 10^5 yr of coagulation. Considering all potential sources of uncertainty, those authors estimate that their tabulated opacities to be accurate to within a factor of two. This implies that also the masses we derive have that overall uncertainty.

3.2. Core: molecular lines

From our observations of the various isotopologues and transitions of CO, we have several ways to obtain an estimate for the excitation temperature of the gas: from line ratios (3–2)/(2–1) (after the appropriate convolution of the higher-frequency data), or from the peak temperature of the (optically thick) ^{12}CO profiles. In the latter case both IRAM (2–1) and JCMT (2–1) and (3–2) data indicate $T_{\text{ex}} \approx 12\text{--}14$ K for the core and the inner flow (Sect. 3.3), and $10\text{--}11$ K for locations outside the flow. This is consistent with the derivation through line ratios, where we find $T_{\text{ex}} \approx 10\text{--}20$ K at line centre for locations in the outflow lobes (assuming both lines to be optically thin), with sometimes $25\text{--}35$ K in the wings. In the case that both lines are assumed optically thick, $T_{\text{ex}} \sim 7$ K at line centre.

3.2.1. Self-absorption

In the central $20'' \times 20''$ of the cloud several of the $^{12}\text{CO}(2\text{--}1)$, $^{13}\text{CO}(2\text{--}1)$ spectra in the IRAM OTF-maps show a central depression in the emission profile. An example of such a “dip” is shown in Fig. 7a. The maps made at IRAM were centred near the location of the YSO, which is embedded in a cocoon, as revealed by the sub-mm continuum emission (see Sect. 3.1). The YSO itself is only visible in the IR (see [Massi et al. 2008](#)), but the conical cavity it has excavated ([Massi et al. 2004](#)) is partly optically visible because the cocoon is slightly tilted towards us (cf. Fig. 1; [Launhardt 2001](#)). It is thus possible that the central depression in the line profiles is the effect of self-absorption caused by a temperature gradient between the warmer gas near the YSO and the cooler gas further away. In the case of self-absorption the original CO profile might then be reconstructed by fitting a Gaussian profile to the sides of the emission profile, excluding the wings (see Sect. 3.4) and the “dip”. Subtracting the fit from the observed profile and multiplying by -1 gives the emission removed from the profile by the self-absorption. The distribution of this “missing” emission is shown in Fig. 8. The dip is strongest at offset $(+3'', +2'')$, well within the half-power radius of the submillimetre emission (see Table 3), and therefore supporting the hypothesis of self-absorption.

CB230 is associated with a well-collimated outflow, which we shall discuss in Sect. 3.4. Here, in Fig. 7b, we show the average of all $^{12}\text{CO}(2\text{--}1)$ spectra in the blue ($\Delta\delta \geq +2''$) and red ($\Delta\delta \leq -6''$) lobes. Note the very steep red (blue) side on the blue (red) spectrum. In Fig. 7c is shown the average of all spectra at $\Delta\alpha = +27''$, well away from the region with the outflow, and therefore representing the quiescent gas. In all spectra three emission components are visible; the ones at -10 and -3 km s^{-1} will be discussed later. The main component of the gas in the globule, at 2.8 km s^{-1} , is very narrow (linewidth $\Delta V \sim 1.35$ km s^{-1}). The dashed lines in Fig. 7 indicate the two peaks in the emission profile in the top panel; they also precisely delimit the quiescent emission. Therefore, the gas at velocities just outside those indicated by the dashed lines already participates in the outflow.

Fig. 7. IRAM data. *Panel a:* a typical $^{12}\text{CO}(2\text{--}1)$ profile near the cloud centre. *Panel b:* average spectrum for $\Delta\delta \leq -6''$ (red continuous profile) and for $\Delta\delta \geq +2''$ (blue histogram). Note the sharp blue- and red edges. *Panel c:* profile of the quiescent emission: the average of all spectra with $\Delta\alpha = +27''$, $-54'' \leq \Delta\delta \leq 50''$. All offsets are relative to the position of the YSO (2MASS coordinates, see Table 1). The dashed lines at 1.9 and 3.4 km s^{-1} bracket both the “dip” in the CO-profile and the emission of the quiescent gas.

3.2.2. Multiline analysis

We observed a number of molecules and transitions towards the position of the YSO and the sub-mm peak (see Sect. 3.1). The spectra are shown in Figs. 9 and 10. The relatively large number of molecular lines observed makes it possible to analyse the data with RADEX⁶, a model for non-local thermodynamic equilibrium (LTE) molecular radiative transfer in an isothermal homogeneous medium. The model requires as input the kinetic temperature, the H_2 number density, the molecular column

Fig. 8. Distribution of the area of the “dip” in the $^{12}\text{CO}(2-1)$ profiles; IRAM data. Contours (lowest(step)highest) are 0.5(0.5)3.5 K km s^{-1} . A Gaussian curve was fitted to each profile (ignoring the “dip” and wings); the fitted profile was subtracted from the original and the result multiplied by -1 . The residual was then integrated between 1.3 and 3.4 km s^{-1} . The filled circle indicates the position of the sub-mm peak (see Figs. 2, 3). Offsets are relative to the 2MASS position of the YSO (see Table 1).

Fig. 9. JCMT data. Spectra of various molecular lines at the position of the YSO. The $\text{H}_2\text{CO}(3_{22}-2_{21})$ transition was not detected and is not shown (see Table 2). The HCN-spectrum has been Hanning-smoothed to a twice lower resolution with respect to the value in Table 2; the rms in the spectrum shown is 0.14 K . The dashed line indicates the velocity of the quiescent gas (2.75 km s^{-1}).

density, and the full width at half maximum (FWHM) of the line; its output is the brightness temperature, the opacity, and the excitation temperature of the lines. The brightness temperature T_b of the lines was estimated from their main-beam brightness

Fig. 10. JCMT data. Spectra of $\text{SO}(6_5-5_4)$ at different positions, indicated in the panels. The positions are the peak of the blue (right) and red lobe (left). Offsets are relative to the position of the YSO (2MASS coordinates, see Table 1). The dashed line as in Fig. 9.

Fig. 11. Probability density function for each couple of values $T_K - n_{\text{H}_2}$, determined using the six lines not affected by self-absorption [$\text{CS}(5-4)$, $\text{HCN}(3-2)$, $\text{SO}(6_5-6_4)$, $o\text{-H}_2\text{CO}(3_{12}-2_{11})$, $p\text{-H}_2\text{CO}(3_{03}-2_{02})$ and $(3_{22}-2_{21})$]. The contours show the 68 and 95% credibility levels.

temperature T_{mb} using

$$T_b = \frac{\vartheta_B^2 + \vartheta_S^2}{\vartheta_S^2} T_{\text{mb}}, \quad (1)$$

where ϑ_B and ϑ_S are the FWHM of the beam and the source, respectively. We assumed that all the transitions come from the same region, estimating the source size from the FWHM of the sub-mm and high-resolution CO observations to be about $20''$.

We built a grid of models with different kinetic temperature (T_{kin}), volume density of molecular hydrogen (n_{H_2}), and column density of the molecule considered, the first two parameters with 51 equal logarithmic steps (from 10 to 200 K, and from 10^3 to 10^7 cm^{-3} , respectively) and the last with 21 (from 5×10^{11} to $1 \times 10^{14} \text{ cm}^{-2}$), respectively. The FWHM of the line is fixed from the observations for each line; only the six lines not affected by self-absorption ($\text{CS}(5-4)$, $\text{HCN}(3-2)$, $\text{SO}(6_5-6_4)$, $o\text{-H}_2\text{CO}(3_{12}-2_{11})$, $p\text{-H}_2\text{CO}(3_{03}-2_{02})$ and $(3_{22}-2_{21})$) were considered. We used a Bayesian approach (Bolstad 2007) to interpret the results (cf. Giannetti et al. 2012). The probability of measuring a certain value for the intensity of a line is assumed to be represented by a Gaussian curve centred on the value obtained from RADEX for specific physical conditions of the gas, and with a σ given by the uncertainty in the measured value. We used a Gaussian prior on the kinetic temperature, with $\mu = 30 \text{ K}$ and $\sigma = 30 \text{ K}$. On the other hand, we used a constant prior for the molecular column density and the volume density of molecular hydrogen.

Figure 11 shows the final probability for each combination of T_{kin} and n_{H_2} . The contours show the 68% and 95% credibility levels. From the marginal probability distributions we find a mean gas temperature $\log(T_{\text{kin}}[\text{K}]) = 1.33$ ($T_{\text{kin}} = 21.4 \text{ K}$), with

Table 4. Methanol lines in the observed band at Onsala.

CH ₃ OH transition	Frequency ⁽¹⁾ (GHz)	E_l (K)	E_u (K)	Type
2 _{-1,2} -1 _{-1,1}	96.739362	7.90	12.54	E
2 _{0,2} -1 _{0,1}	96.741375	2.32	6.97	A+
2 _{0,2} -1 _{0,1}	96.744550	15.45	20.09	E
2 _{1,1} -1 _{1,0}	96.755511	23.37	28.01	E

Notes. ⁽¹⁾Frequencies taken from the splatalogue data base (<http://www.cv.nrao.edu/php/splat/>).

a 68% credibility interval for $\log(T_{\text{kin}}[\text{K}])$ between 1.16 – 1.55 ($14.5 \leq T_{\text{kin}} \leq 35.5$ K), and a volume density $\log(n_{\text{H}_2}[\text{cm}^{-3}]) = 5.66$, with a 68% credibility interval for $\log(n_{\text{H}_2}[\text{cm}^{-3}])$ between 4.92 – 5.96.

The lines of HCO⁺ are self-absorbed, and thus their line temperatures are rather uncertain. We can reconstruct the original line profile by fitting a Gaussian while masking the self-absorbed channels. When we include these lines in the calculations, we take into account a larger uncertainty, given by the difference between the measured line temperature and the one from the reconstructed profile. This then gives $\log(T_{\text{kin}}[\text{K}]) = 1.33$ ($T_{\text{kin}} = 21.4$ K), and $\log(n_{\text{H}_2}[\text{cm}^{-3}]) = 5.77$, with a 68% credibility intervals for the logarithmic quantities between 1.05 and 1.52 ($10.5 \leq T_{\text{kin}} \leq 33.1$ K) and 5.00 and 6.20, respectively.

3.2.3. Larger scale

With the various telescopes we mapped the core of CB230 and its immediate surroundings. In Fig. 12 we show the larger-scale emission of C¹⁸O(1–0), CS(2–1) and CH₃OH(2_k–1_k) mapped with the Onsala telescope. The three tracers have remarkably different distributions, although they all show an elongated structure; the elongation is roughly perpendicular to the direction of the outflow (see Sect. 3.4). The contours at half the peak value indicate a flattening of a factor of 1.5–1.7 (extent in RA/extent in Dec); the area under this contour gives an equivalent beam-corrected core diameter of 0.16 pc (CH₃OH) or 0.21 pc (C¹⁸O, CS).

With $T_{\text{ex}} \approx 15$ K and assuming C¹⁸O is optically thin, we derive from the detection equation that $\tau[\text{C}^{18}\text{O}(1-0)] \approx 0.18$ for the average C¹⁸O spectrum inside the half-maximum contour and an average column density of $N(\text{C}^{18}\text{O}) = 1.5 \times 10^{15} \text{ cm}^{-2}$. Using $[\text{C}^{18}\text{O}]/[\text{H}_2] = 1.7 \times 10^{-7}$ (Frerking et al. 1982), the average $N(\text{H}_2) = 9.0 \times 10^{21} \text{ cm}^{-2}$. The total molecular mass inside the FWHM contour is therefore about $7.6 M_{\odot}$, including a correction ($\times 1.36$) for helium and metals. With an average C¹⁸O linewidth of 0.60 km s^{-1} inside the FWHM-contour (which has an equivalent radius of 0.11 pc), we derive a virial mass of 5.0 or $8.3 M_{\odot}$ for a density distribution $\propto r^{-2}$ or constant, respectively.

Likewise we find $N(\text{CS}) \approx 3.6 \times 10^{12} \text{ cm}^{-2}$ (assuming CS(2–1) is optically thin) and a mass inside the FWHM contour of $3.30 \times 10^{-9} ([\text{CS}]/[\text{H}_2])^{-1}$. With an abundance $[\text{CS}]/[\text{H}_2] = 2.0 \times 10^{-9}$ (Zhou et al. 1991) we get $M \approx 1.7 M_{\odot}$, which is likely a lower limit because the CS profiles in the core-region suffer from self-absorption. Correcting for optical depth would increase this lower limit by a factor of 1.6–2.3 for $\tau = 1-2$, respectively.

Table 4 lists the methanol lines that fall within the bandwidth of the Onsala spectra. Where a detection was made, the two lower frequency lines were virtually always detected together

Fig. 12. Onsala data. *Panel a:* C¹⁸O(1–0) $\int T_{\text{mb}} dv$. Lowest contour and step: 0.6 and 0.2 K km s⁻¹; *panel b:* CS(2–1) $\int T_{\text{mb}} dv$ (colour scale and black contours; lowest contour and step: 0.35, 0.2 K km s⁻¹) with CH₃OH(2–1) $\int T_{\text{mb}} dv$ (white contours; lowest contour and step: 0.15 K km s⁻¹) superimposed; the combined area under the two emission lines with the lowest upper level temperature (E and A+; Table 4 and Fig. 14) are shown. The red and blue arrows indicate the approximate direction of the outflow detected in CO(3–2) (see text). The small white crosses indicate the positions where both CS and CH₃OH were observed; the black dots are for CS only. *Panel c:* CH₃OH(2–1) $\int T_{\text{mb}} dv$ for the A+ component (see Fig. 14) only. Lowest contour and step: 0.15, 0.1 K km s⁻¹. *Panel d:* as c, but for the E-component only. In all panels, the white cross indicates the position of the 850 μm peak, which is also that of the embedded YSO. All offsets are relative to the 2MASS YSO position (see Table 1).

Fig. 13. IRAM data. ^{12}CO , ^{13}CO , CS, and SO $\int T_A^* dv$, integrated between 1.5 and 3.9 km s^{-1} (avoiding the line wings caused by outflow). From left to right: contours low(step)max: 3(1)11 K km s^{-1} (^{12}CO); 1(0.5)4.5 K km s^{-1} (^{13}CO); 0.15(0.15)1.05 K km s^{-1} (CS); and 0.15(0.15)0.80 K km s^{-1} (SO). The white dot indicates the location of the $850\ \mu\text{m}$ peak. The white crosses in the leftmost panel indicate the positions where CH_3OH was observed. All offsets are relative to the 2MASS YSO position (see Table 1).

(except at offset $(42'', -40'')$, where only the A+ component was detected). The third line in the table was detected only at offset $(4'', 74'')$. In Fig. 12b the contours for methanol indicate the sum of the emission all detected lines, while in Figs. 12c and d we show the integrated emission for the A+ and E-components separately. The latter has an upper energy level almost twice as high as the former, and its emission is more concentrated around the YSO; the A+ component on the other hand, has a more elongated distribution. Methanol is commonly detected in dark clouds; it is expected to be enhanced in regions with shocks, but there is no sign of this along the large-scale CO outflow (cf. Fig. 12b). In fact we see that the $\text{CH}_3\text{OH}(2-1)$ emission peaks at the YSO-position and is more extended perpendicular to the outflow direction.

3.2.4. Smaller scale

The smaller-scale maps made with the IRAM 30-m telescope (Fig. 13) confirm the differences in gas distribution seen on the larger-scale. While the $^{12}\text{CO}(2-1)$ and $^{13}\text{CO}(2-1)$ emission have a maximum also at the location of the YSO, the CS(2-1) does not; CS, a tracer of volume density, has a reduced presence in the cavity cleared out by the outflow at the location of the YSO. At the same time, the CS(2-1) profiles show signs of self-absorption in the vicinity of the YSO, which also reduces the integrated intensity. (cf. Fig. 2 in Tobin et al. 2010, where the extinction, represented by the optical depth at $8\ \mu\text{m}$, is higher and more extended to the West of the YSO). Interestingly, in both ^{12}CO and ^{13}CO we find the peak at about $10''$ east of the YSO, which coincides with the location of the NIR source found by Yun & Clemens (1994b) and resolved as binary source CB230-B1 and -B2 by Massi et al. (2004).

With the IRAM 30-m telescope we made higher-resolution and deeper observations of both $\text{CH}_3\text{OH}(2-1)$ and $(5-4)$ at ten positions, along two parallel strips (see Sect. 2.1.2). The two lowest-excitation lines were detected everywhere, while a third component was clearly detected at the position of the YSO

and only marginally at a few other locations. The $(5-4)$ transition was detected nowhere. With only 2 or even 3 detected lines it is difficult to determine the physical parameters of the gas. Nevertheless we fitted synthetic spectra to the observations, using MCWeeds (Giannetti et al. 2017). This program allows one to simultaneously fit lines from an arbitrary number of species and components, in multiple spectral ranges, assuming LTE conditions. We ran MCWeeds on the single spectrum at the YSO position as well as on the average spectrum of those positions where the third emission component of the $(2-1)$ transition was (marginally) detected (see Fig. 14). The $(5-4)$ spectrum was also used by the routine; even though no lines were detected, this serves to constrain the kinetic temperature. The results are quite similar, and we only show those for the average spectrum, in Fig. 14. The fit results are $T_{\text{ex}} \approx 7.6 \pm 0.6\ \text{K}$, $\log(N) \approx 13.40 \pm 0.07$, but it is clear from the lower panel of the figure, that the fit is not good: it overestimates the intensity of the higher-frequency E-line and severely underestimates that of the lower-frequency E-component. This implies that either methanol is not in LTE and/or that the various components come from regions of different temperature and density.

Several other molecules have been observed on the same 2×5 grid (see Table 2 and Sect. 2.1.2): SiO(2-1) and $\text{H}_2\text{S}(2_{20}-2_{11})$ have not been detected anywhere, while $\text{H}^{13}\text{CO}^+(1-0)$ has been detected at all positions except the bottom row ($\Delta\delta = -34''$). This line was detected in the low-resolution broadband backend of the SiO(2-1) observations. Because of the poor velocity resolution ($3.45\ \text{km s}^{-1}$) the emission is in only one channel. The rms-values of the non-detections translate into an upper limit to the column densities of $1.0 \times 10^{12}\ \text{cm}^{-2}$ for SiO, and $1.8 \times 10^{13}\ \text{cm}^{-2}$ for H_2S . These are 3σ limits calculated using Weeds, from $\int T_{\text{mb}} dv$ when integrating over $2\ \text{km s}^{-1}$, and assuming $T_{\text{ex}} = 100\ \text{K}$. A high value for the temperature is used here, because these molecules are produced by sputtering or shattering of dust refractory cores.

With the JCMT we observed SiO(5-4) at 5 positions in the molecular outflow (see Sect. 3.4; 3 in the blue lobe, 2 in the red

Fig. 14. IRAM 30-m data. *Top panel:* average $\text{CH}_3\text{OH}(2-1)$ spectrum of observations at 6 positions in which the three indicated lines are detected. The spectrum has been smoothed to a resolution of 0.484 km s^{-1} ; $\text{rms} = 0.014 \text{ K}$. *Bottom panel:* fit (in red) to the same average spectrum (at original resolution of 0.242 km s^{-1} , and shown in frequency scale). See text for details.

lobe); no emission was detected. These non-detections imply a 3σ upper limit to the column density of about $7.1 \times 10^{11} \text{ cm}^{-2}$ (from Weeds; and $T_{\text{ex}} = 100 \text{ K}$).

Massi et al. (2008), from [FeII]-spectral lines, estimated the hydrogen volume density in the knots in the jet to be $n_{\text{H}} \sim 10^4 - 3 \times 10^5 \text{ cm}^{-3}$. Considering that the size of, for example, knot k1 is $\sim 1''.2$ (Massi et al. 2004), this implies a column density of $\text{N}(\text{H}) \sim 6 \times 10^{19} - 1.8 \times 10^{21} \text{ cm}^{-2}$ (for $d = 339 \text{ pc}$). In shocks the abundance of SiO can be very much enhanced relative to its abundance in the quiescent medium; for example in dark cloud L1448 it reaches values of a few $\times 10^{-7}$ in the outflow driven by the embedded low-mass protostar (Bachiller et al. 1991). The above-mentioned range of $\text{N}(\text{H})$ would then imply $\text{N}(\text{SiO}) \sim 10^{12} - 10^{14} \text{ cm}^{-2}$, higher than the upper limits estimated above. It is possible that SiO is present in the jet, but is undetected with the JCMT because of beam dilution.

3.3. Velocity gradient

Figure 15 shows that the C^{18}O emission has a velocity gradient across the core. The figure shows the line velocities as a function of $\Delta\alpha$ at $\Delta\delta = 0''$, which is roughly perpendicular to the north-south orientation of the outflow (see Sect. 3.4). In these Onsala data this tracer shows a small gradient, with velocities being bluer on the western side of the core. The gradient is $0.98 \text{ km s}^{-1} \text{ pc}^{-1}$; if this were to be taken as rotation, this would correspond to an angular velocity $\omega \approx 3.2 \times 10^{-14} \text{ s}^{-1}$. This puts CB230 somewhere near the region of “fast” rotators, according to the distribution found by Kane & Clemens (1997) for starless Bok globules. We note that we are not able to determine a trustworthy velocity gradient using the IRAM CS-data,

Fig. 15. Onsala data. $\text{C}^{18}\text{O}(1-0)$ velocity (from Gaussian fit to line profiles) at $\Delta\delta = 0''$ vs. $\Delta\alpha$ (see Fig. 12a). Drawn line is best fit, and indicates velocity gradient of $0.98 \text{ km s}^{-1} \text{ pc}^{-1}$. Offsets are relative to the position of the YSO (2MASS coordinates, see Table 1).

because many line profiles in the central region suffer from self-absorption, making it difficult to determine an accurate velocity of the actual, unaffected profile.

Velocity gradients in the core have been detected before, in $\text{N}_2\text{H}^+(1-0)$ (Chen et al. 2007; Tobin et al. 2011) and $\text{NH}_3(1,1)$ (Tobin et al. 2011). On the large-scale, comparable to that in Fig. 15, the single-dish N_2H^+ observations by Tobin et al. (2011), scaled to a distance of 339 pc , show a gradient of about $2.3 \text{ km s}^{-1} \text{ pc}^{-1}$, with velocities decreasing from east to west (cf. Fig. 15). However, when measured over the inner $20'' - 40''$, the gradients are $-2.8 \text{ km s}^{-1} \text{ pc}^{-1}$ for the single-dish N_2H^+ observations (Tobin et al. 2011) and of the order of -10.4 to $-9.7 \text{ km s}^{-1} \text{ pc}^{-1}$ from the interferometric observations of N_2H^+ (Chen et al. 2007) and NH_3 (Tobin et al. 2011), all when scaled to a distance of 339 pc . The minus sign indicates a change in direction of the velocity gradient; in the inner $\pm 10'' - 20''$ around the YSO, the velocities increase from east to west. This reversal of velocity gradient on the small scale indicates that the disk around the protostellar binary is apparently physically decoupled from the rest of the cloud.

With the measured gradient of $V_{\text{grad}} = 0.98 \text{ km s}^{-1} \text{ pc}^{-1}$, the ratio of the rotational kinetic energy and gravitational energy is $\beta = (1/3)(V_{\text{grad}}^2 R^3)/(GM) \approx 1.3 \times 10^{-2}$, for a homogeneous spherical core; for a core with a density $\propto r^{-2}$ this would be three times smaller (Goodman et al. 1993). Likewise the rotational kinetic energy is only a small fraction ($\approx 1\%$) of the turbulent energy ($E_{\text{turb}} = (1/2)M\Delta V^2$; $\Delta V \sim 0.6 \text{ km s}^{-1}$ for C^{18}O). It is thus clear that rotation is not relevant for the energy budget of the cloud (-core).

3.4. Large-scale outflow

The average $^{12}\text{CO}(2-1)$ spectrum of the quiescent cloud emission in Fig. 7c shows that in addition to the main emission component at $\sim 2.7 \text{ km s}^{-1}$ there is also emission at approximately -10 and -3 km s^{-1} . The outflowing gas is characterised by broad wings on the line profiles that can extend out to -7 and $+14 \text{ km s}^{-1}$, and thus at certain locations in the map includes the -3 km s^{-1} component. The -10 km s^{-1} component is well outside the range of the blue wing emission, and is clearly not connected to CB230 as it peaks outside (to the SE) the region mapped here. Inside the mapped region it has an irregular distribution (see Fig. 16). Emission at -3 km s^{-1} is not very strong

Fig. 16. IRAM data. Distribution of $T_A^* [^{12}\text{CO}(2-1)]$ of the -10 km s^{-1} component. Contours (lowest(step)highest) are 0.5(0.25)3.0 K. It peaks towards the SE of the map, and is unrelated to the molecular gas in the globule, which is at $V_{\text{lsr}} \sim 2.8 \text{ km s}^{-1}$. The black dot indicates the position of the sub-mm peak, see Figs. 2, 3). Offsets are relative to the 2MASS YSO position (see Table 1). The YSO is located in the layer of least-intense emission of this component.

and does not significantly contribute to the total emission in the blue wings, but including this velocity component in the integral over the line wings outside the region of the outflow leads to regions of enhanced blue-wing emission which is not real as it is not part of the blue wing at all. We have therefore Gaussian-fitted and removed this component from all spectra where it was clearly separate from the blue wing.

The map of the outflow emission is shown in Fig. 17. Integration limits in velocity were chosen such that they exclude the emission of the quiescent gas. To determine the velocity at which the gas may be considered to partake in the outflow, we have fitted a Gaussian curve to the line profile at the centre using a mask that excludes both the self-absorption dip and the extended wings, see Fig. 18. This should more or less reproduce the original emission profile. The velocities at which the quiescent emission ends were then taken to be those at which the Gaussian profile reaches the half-intensity value.

The blue lobe is much more extended than the red one; this may indicate that the outflow is somewhat tilted towards us causing us to have a protracted view of the gas at red-shifted velocities. On the other hand, a glance at Fig. 1 suggests that this could also be because south of the YSO the edge of the globule is reached sooner than in the north, so there simply is no more material to participate in the outflow. An overlay in Fig. 1 in [Massi et al. \(2008\)](#): there is a directional offset between the position angle of the jet seen in [FeII] emission, and that of the large-scale molecular outflow, of about 15° . The light cone seen

Fig. 17. JCMT data. *Left panel:* distribution of $\int T_A^* dv$ of $^{12}\text{CO}(3-2)$ between -6 and 1.37 km s^{-1} (blue wing; drawn contours) and between 4.68 and 14 km s^{-1} (red wing; dashed contours). Lowest contour and step are 1 K km s^{-1} . The black square indicates the peak of the $850 \mu\text{m}$ emission. The green dots indicate where $\text{C}^{18}\text{O}(2-1)$ spectra were taken along the outflow axis (see Fig. 21). *Right panel:* $^{13}\text{CO}(3-2)$ outflow. Integration intervals are from -0.5 to 2.12 km s^{-1} (blue wing; drawn contours) and from 3.68 to 6.0 km s^{-1} (red wing; dashed contours). Lowest contour and step are 0.2 K km s^{-1} . All offsets are relative to the 2MASS YSO position (see Table 1).

Fig. 18. Gaussfit to the emission profile of $^{12}\text{CO}(3-2)$ at the centre position of the outflow ($-8'', 0''$). A mask was used as indicated to exclude the self-absorption dip and the extended line wings.

in Fig. 1 lies more or less in the same direction as the [FeII]-jet, while the molecular outflow hugs the western edge of the light cone. This misalignment suggests that perhaps the outflow has changed direction with time: the current molecular flow is the material swept up when the jet was pointing in that direction; when the jet precesses it takes time before enough new cloud material is being entrained and becomes detectable. This causes an offset between the jet and the central axis of the molecular outflow.

We calculated the parameters of the outflowing gas, by assuming LTE-conditions and optically thin gas. The results are shown in Table 5. We considered two values of T_{ex} (see

Table 5. Parameters of the molecular outflow associated with CB230.

Notes. Using the abundance ratio $[\text{CO}]/[\text{H}_2] = 1.0 \times 10^{-4}$.

Sect. 3.2) and used T_{mb} . The total velocity intervals over which we integrated are -5.63 to 1.37 km s^{-1} (blue wing) and 4.68 – 13.68 km s^{-1} (red wing). Integration was done in 1 km s^{-1} -wide bins; emission with $S/N = 3$ and 2 was taken into account, respectively (top and bottom parts in Table 5). In addition to the mass of the material participating in the outflow, we also calculated the flow’s momentum, energy, size and velocity (cf. Wouterloot & Brand 1999; Lada 1985). The dynamical age (t_{dyn}) was then derived from the ratio of the size of the flow and its velocity. The age was used to derive the force F_{m} (=Momentum/age) required to drive the outflow and the mechanical luminosity L_{m} (=Energy/age). It is no surprise that this low-mass dark cloud and its low-mass YSO (0.2 – $0.5 M_{\odot}$, Froebrich 2005; $\sim 0.3 M_{\odot}$, Massi et al. 2008; all scaled to 339 pc) are associated with a low-mass outflow, with $M_{\text{tot}} \approx (1$ – $3) \times 10^{-2} M_{\odot}$ (~ 0.1 – 0.4% of the core mass), depending on the value of T_{ex} .

In these calculations we have not taken into account the inclination of the outflow with respect to the plane of the sky. For an inclination angle i the correction in outflow velocity is $1/\sin(i)$, while the size of the flow should be corrected by $1/\cos(i)$. The derived age would change by a factor of $\tan(i)$. So for $i = 30^\circ$ the flow would be 42% younger, and for $i = 60^\circ$ (less likely) it would be 73% older. Momentum and energy would need to be adjusted by a factor of $1/\sin(i)$ and $(1/\sin(i))^2$, respectively. The masses need no correction.

By comparing the momentum flux of the atomic jet, seen in [FeII]-emission, and that of the larger-scale molecular outflow, Massi et al. (2008) have concluded that the jet is capable of driving the molecular outflow. If the outflow has a semi-aperture angle θ , then the fraction of the (spherical) core mass that is swept away by the jet is $\frac{1}{2}(1-\cos\theta)$ for each of the lobes. The total mass in the outflow is ($T_{\text{ex}} = 15 \text{ K}$; emission $> 3\sigma$) $M_{\text{tot}} \sim 1.4 \times 10^{-2} M_{\odot}$, which is 0.18% of the core mass ($8 M_{\odot}$; Sect. 3.1, Fig. 6). This implies $\theta \approx 3.4$ and an opening angle of 6.8 . For the (more massive) blue lobe alone the opening angle is found to be 8.2 . That is approximately the same as the angle subtended by knot k1 in the jet (see Massi et al. 2004), as seen from the YSO. The total angle covered by the cone of [FeII]-emission is about 63° ; if, as mentioned earlier, the outflow has changed direction with time, this may be the angle that the jet has swept out, not necessarily the opening angle of the outflow. Some of the mass in the large-scale outflow does not come from the core but is swept-up cloud material. Considering the blue lobe, and assuming that

Fig. 19. JCMT data. Comparison of spectra at the location of the YSO (coinciding with the centre of the outflow and the sub-mm continuum peak). *Panel a:* $^{12}\text{CO}(3-2)$ spectrum (broad emission line; taken from the mapping data). The weaker, narrow blue line is the average of 45 spectra in the $^{12}\text{CO}(3-2)$ -map, with $\alpha > 25''$, well away from the outflow and hence representing the quiescent gas. The dashed line indicates its central velocity (2.75 km s^{-1}), which corresponds with that of the dip in the line profile at the centre of the outflow, while the width of the dip is virtually identical to the fwhm of the quiescent gas profile. *Panel b:* deep $J=3-2$ spectra of three CO-isotopologues. Only C^{18}O (red) does not show a self-absorption dip. The velocity of its peak nearly coincides with the central velocity of the quiescent gas in panel a.

30–50% of the mass in the outflow is swept-up ambient cloud material, we find an opening angle of 6° – 7° , still very similar to the jet-angle.

Figures 19 and 20 (deep integrations towards 4 selected positions in the outflow; JCMT data) show the narrowness of the quiescent gas emission [$\Delta V_{\text{FWHM}} \sim 1 \text{ km s}^{-1}$ for $\text{C}^{18}\text{O}(2-1, 3-2)$]. In these higher-resolution spectra (compared to the ones in Fig. 7) we also see that the velocity of the self-absorption dip

Fig. 20. JCMT data. Comparison of $J=3-2$ (left) and $J=2-1$ (right) spectra at four positions of ^{12}CO (black), ^{13}CO (blue), and C^{18}O (red). The widest and most intense emission is that of ^{12}CO , the narrowest and weakest emission profile is that of C^{18}O . The dashed line indicates the velocity (2.75 km s^{-1}) of the quiescent gas (see Fig. 19). The offsets relative to the 2MASS YSO position are indicated in the left-hand panels (see also Fig. 17).

is actually slightly redder than the velocity of the quiescent gas. This could be a sign of infalling cooler gas from the envelope. The spectra in Fig. 20 show that the outflow is only clearly visible in ^{12}CO , although Fig. 17 shows that also ^{13}CO profiles have detectable red- and blue-shifted emission.

In Fig. 17 we have indicated several locations along the outflow lobes where we have obtained $\text{C}^{18}\text{O}(2-1)$ spectra. These are shown in Fig. 21. We have made Gaussfits to these spectra; the average velocities in the red lobe ($2.882 \pm 0.042 \text{ km s}^{-1}$) are redder than those in the blue lobe ($2.744 \pm 0.069 \text{ km s}^{-1}$), but no velocity gradient along the outflow lobes is detected.

4. Summary

We have carried out a multi-molecular line and sub-mm continuum study of globule CB88 230 (CB230 for short) with various single-dish antennas. The aim was to study the molecular outflow associated with the jet we discovered emanating from the YSO (Massi et al. 2004), as well as the cloud surrounding the YSO, a low-mass ($\sim 0.3 M_{\odot}$; scaled to a distance of 339 pc) Class 0/I object (Massi et al. 2008). CB230 is found to have a flattened core, material distributed asymmetrically with respect to the embedded YSO and showing self-absorbed line profiles, that may indicate infalling colder gas from the envelope. The YSO is associated with a low-mass bipolar outflow with the northern

Fig. 21. JCMT data. $\text{C}^{18}\text{O}(2-1)$ spectra taken along the CO-outflow axis (see Fig. 17). Dashed line as in Fig. 19. Offsets are in arcsec relative to the 2MASS YSO position (see Table 1).

(blue) lobe tilted towards the observer, allowing a partially unobscured look into the cone excavated by the flow. Our main results can be summarised as follows:

Larger-scale line maps (C^{18}O , CS, CH_3OH) show a flattened core structure (ratio 1.5–1.7), with equivalent beam-corrected diameter 0.16–0.21 pc. Also the submillimetre dust continuum observations show a flattened structure, an equivalent diameter (at $850 \mu\text{m}$) of $\sim 0.16 \text{ pc}$, and an asymmetry with respect to the YSO. This asymmetry is also visible in the line maps of CS, SO and C^{18}O .

The line ratios of optically thin lines indicate an excitation temperature of 10–20 K as does the line intensity of the optically thick ^{12}CO -lines. A fit to the SED results in a dust temperature of $\sim 18 \text{ K}$.

A multi-line analysis of molecules observed towards the YSO, using Bayesian approach finds a mean gas temperature of 21.4 K (with a rather large 68% credibility interval of 14.5–35.5 K), and an H_2 volume density $n \approx 4.6 \times 10^5 \text{ cm}^{-3}$ (8.3×10^4 – 9.1×10^5).

Assuming LTE-conditions, we find a molecular mass inside the FWHM contour of $M \approx 8 M_{\odot}$, from our $\text{C}^{18}\text{O}(1-0)$ observations. The virial mass is ~ 5 – $8 M_{\odot}$, depending on the assumed density distribution. From modelling the dust-continuum observations we find a total gas mass of $8 M_{\odot}$, assuming a gas-to-dust ratio of 100. The SED fit yields about $2 M_{\odot}$, which is likely too low because the SED is dominated by the emission from the relatively hot central region (and higher temperature leads to lower mass-estimates).

Line profiles of ^{12}CO , ^{13}CO , HCO^+ and $\text{CS}(2-1)$ in the immediate vicinity of the YSO show self-absorption. Observations at higher velocity-resolution show that the self-absorption dip is at a slightly redder velocity than that of the quiescent gas emission, suggesting infall of cooler gas.

A well-collimated molecular outflow is associated with the YSO. We mapped the outflow in $^{12}\text{CO}(3-2)$. Away from the flow-region, the profiles of the quiescent gas are quite narrow ($\sim 1 \text{ km s}^{-1}$). The blue lobe is longer than the red lobe, most likely because the edge of the globule is nearer to the YSO towards the south than towards the north and there just is no more material to participate in the flow.

The flow has a dynamic age of a few 10^4 yr, and contains very little mass (a few $10^{-2} M_{\odot}$). The calculated age depends on the inclination angle i of the flow relative to the plane of the sky as $\tan(i)$. A misalignment of $\sim 15^\circ$ between the axis of the molecular outflow and the direction of the hot jet detected previously (see [Massi et al. 2004](#)) suggests a change in outflow direction (precession) with time. The mass of the gas participating in the outflow is consistent with the fraction of the core-mass being swept away by the jet as seen in $[\text{FeII}]$, with an opening angle of $\sim 8^\circ$, even when taking into account that a large fraction of the outflow mass is entrained ambient cloud material.

Molecules, such as H_2S and SiO , that are expected to show an enhanced abundance in regions where shocks occur (e.g. where the fast jet hits the ambient medium), have not been detected. The non-detections imply upper limits to the column densities of $1.0 \times 10^{12} \text{ cm}^{-2}$ for SiO and $1.8 \times 10^{13} \text{ cm}^{-2}$ for H_2S . The non-detection of $\text{SiO}(5-4)$ at several locations in the outflow implies an upper limit of the column density of $\sim 7.1 \times 10^{11} \text{ cm}^{-2}$. Only $\text{SO}(6_5-5_4)$ has been (marginally) detected at two locations in the outflow, though still near the YSO.

A modest velocity gradient ($0.98 \text{ km s}^{-1} \text{ pc}^{-1}$) is detected in C^{18}O , roughly perpendicular to the outflow axis. If this is core-rotation, a comparison with gravitational and turbulent energy shows that rotation is not relevant for the energy budget of the core (only $\sim 1\%$ of the total energy).
