Phytostabilization of Pb tailing

Pb immobilization

Microbial diversity

15

16

17 **Abstract**

18 Old mine waste repositories can present health and/or environmental issues linked to their
19 erosion, inducing dissemination of metals and metalloids in air and water that can be attenuated
20 through phytostabilization. Here, the effect of this widespread phytomanagement option on the
21 biogeochemistry of a Pb-rich mine waste was evaluated with a laboratory pilot-scale experiment
22 giving access to the non-saturated and saturated zones below the rhizosphere compartment.
23 Amendment of the tailings surface with biochar, manure and iron-oxide-rich ochre promoted
24 growth of the seeded *Agrostis capillaris* plants. These events were accompanied by an increase
25 of pH and a decrease of Pb concentration in pore water of the surface layer, and by a transient
26 increase of Pb, Zn, and Ba concentrations in the deeper saturated levels. Macroscopic and
27 microscopic observations (SEM) suggest that Pb was immobilized in *A. capillaris* rhizosphere
28 through mechanical entrapment of tailing particles. Microbial taxonomic and metabolic
29 diversities increased in the amended phytostabilized surface levels, with an increase of the
30 proportion of heterotrophic micro-organisms. Below the surface, a transient modification of
31 microbial communities was observed in the non-saturated and saturated levels, however 11
32 months after seeding, the prokaryotic community of the deepest saturated zone was close to that
33 of the initial tailings. pH and water saturation seemed to be the main parameters driving
34 prokaryotic communities' structures. Results obtained at pilot-scale will help to precisely
35 evaluate the impacts of phytostabilization on the temporal evolution of reactions driving the
36 fate of pollutants inside the tailings dumps.

37

38 **Key words:** mine tailings, metals, assisted phytostabilization, laboratory pilot, microbial
39 diversity.

40 **1 Introduction**

41 Unrestored mine tailing sites are a worldwide problem since they generally remain bare for
42 decades or even centuries. For abandoned mine tailing heaps, the establishment of a
43 spontaneous vegetation cover is usually considered beneficial as it represents a sort of
44 phytostabilization (Houben et al., 2013). Indeed, revegetation of these degraded sites appears
45 as a suitable long-term solution: the plant cover limits eolian dispersion, while the roots prevent
46 water erosion and leaching, and provide a rhizosphere wherein metals can precipitate and
47 stabilize (Mendez and Maier, 2008). However, for lead (Pb)/zinc (Zn) mine sites, metal toxicity,
48 especially available Pb, nutrient deficiency, and poor physical structure of the substrate are
49 major constraints for plant establishment and colonization (Ye et al., 2002). Therefore, a
50 suitable strategy consists of aided phytostabilization by using pioneer plants (Lago-Vila et al.,
51 2019) coupled with efficient organic and inorganic amendments (Sikdar et al., 2020).

52 In this context, numerous laboratory studies with pot experiments have recently been devoted
53 to test the efficiency of plants and several amendments, alone or in combination, on Pb and Zn
54 retention and plant growth in mine tailings (Ciarkowska et al., 2017; Al-Lami et al., 2019;
55 Norini et al., 2019; Gao et al., 2020). Although different combinations may rapidly be tested,
56 these pot experiments only focused on plant biomass and metal availability in the rhizosphere
57 area, and are far from the field scale.

58 Other small-scale experiments include laboratory percolation tests enabling to measure/assess
59 the transfer of contaminants through mine residues and to evaluate the effect of amendments
60 (Rodriguez et al., 2018; Thouin et al., 2019), whereas influence of water saturation can be
61 studied in columns (Ouangrawa et al., 2010). These systems are well constrained and they give
62 insight on small-scale processes but it is necessary to increase the scale in order to understand
63 interactions between different compartments and reflect field conditions.

64 In this regard, field experiments have been conducted to optimize the combination of plants and
65 amendments in phytostabilization of metal(loid)s pollutants in mine sites (Yang et al., 2016;
66 Acosta et al., 2018; Li et al., 2019). However, some key parameters could not be precisely
67 controlled and accounted for, such as soil water saturation and incoming water flow. Moreover,
68 some types of samples, such as pore water at different depths are difficult to collect during on-
69 site studies and spatial heterogeneities of mine tailings often represent an obstacle for the
70 interpretation of results obtained on-site (Constantinescu et al., 2019).

71 To overcome these limitations, lysimeters directly installed in the field give access to real
72 conditions of watering, temperature and light, and allow the possibility to sample percolated
73 water (Nicoara et al., 2014; Bilibio et al., 2017; Constantinescu et al., 2019). In such systems, ,
74 some environmental factors cannot be controlled. Mesocosm scale laboratory pilot
75 experiments, as an intermediary step between pot and field experiments, combine the advantage
76 of controlled conditions of temperature, watering and water saturation with the possibility of
77 simultaneously observing the amended and planted surface levels (Valentin-Vargas et al., 2014)
78 and the underlying non saturated and saturated zones (Thouin et al., 2017; 2018).

79 Among the multiple parameters evaluated during these multi-scale experiments, microbial
80 communities can give indications on the biogeochemical processes. Phytostabilization always
81 induces modifications of the microbial diversity and metabolic profiles in the mining wastes
82 colonized by plants, amended or not (Asemaninejad et al., 2020). The ability of diverse bacterial
83 and fungal species to thrive in mining residues improves soil functions and encourages
84 sustainable plant growth (Harris et al., 2009). Common effects of phytostabilization on
85 microbial diversity were observed in diverse conditions of amendments and plants species, both
86 in greenhouse experiments (Mendez et al., 2007, You et al., 2018) or field conditions (Li et al.,
87 2015; Asemaninejad et al., 2020). They include increases in microbial diversity, biomass and
88 relative increase of heterotrophic/organotrophic genera versus litho-autotrophic organisms.

89 These last organisms, mainly sulfur and iron oxidizers, are common hosts of mining wastes and
90 contribute to environmental issues linked to production of sulfuric acid and mobilization of
91 metals, thus a decrease of their abundance and activity in mine waste dumps, during
92 phytostabilization, should be beneficial (Valentín-Vargas et al., 2018).

93 However, most of the previous studies provided data on the microbial communities of the
94 surface environment, in the rhizosphere, and in the close non saturated zones. Thus, the
95 influence of re-vegetation on the underlying microbial communities and on the main
96 biogeochemical cycles driving the fate of pollutants in the depth of the heaps is not well
97 documented.

98 A methodology to promote stabilization of metals and plant growth with amendments, in the
99 surface of aged tailings from a former lead (Pb)-silver (Ag) mine tailing, was previously
100 developed through microcosm scale experiments (Thouin et al., 2019). The objectives of the
101 present laboratory pilot experiment were to evaluate in environmental compartments rarely
102 studied, from the surface to the water saturated level, the influence of amendments and plants
103 growth on temporal evolution of (1) pore water physico-chemistry, and (2) microbial diversity
104 along the vertical profile of this tailing.

105

106 **2 Material and methods**

107 **2.1 Characteristics of the mine tailings, the amendments and the plants**

108 Tailings from the site of the former Ag and Pb mine at Pontgibaud (Puy de Dôme, France) were
109 used for the pilot-scale experiment. Mine tailings were sampled to a depth of 0–60 cm from a
110 mine waste heap, using a power shovel (SM1a). Residues were taken in 7 discrete zones within
111 a 25 m² area. The material was homogenized and sieved at 2 cm; it presented the following
112 particle size distribution: 7% (by weight) < 60 μm, 15% in the 60–315 μm range, and 78% >315

113 μm . The detailed characteristics of this moderately acidic sandy material are given in Thouin
 114 et al. (2019) and Table 1. The pH of the tailings – consisting mainly of quartz, orthoclase and
 115 phyllosilicate – was 4.9 (measured in water according to ISO 10390). Tailings contain about
 116 2.6% Pb and Pb bearing phases were detected by X-ray diffraction (XRD): anglesite (PbSO_4)
 117 and beudantite ($(\text{PbFe}_3(\text{AsO}_4)(\text{SO}_4)(\text{OH})_6$).

118 *Table 1. Main chemical characteristic of the tailings, ochre, manure and biochar. (a) pH was measured in water according to*
 119 *ISO 10390. (b) Element concentrations in solids were analyzed by high resolution inductively coupled plasma mass*
 120 *spectrometry and elemental flash pyrolyser. (c) Standard leaching test was performed with demineralized water according to*
 121 *ISO/TS 21268–2. Pb, Ba and As were analyzed by oven atomic absorption spectroscopy, and Fe and Zn by flame atomic*
 122 *absorption spectroscopy. DOC and DON were determined using a TOC elemental analyzer.*

123 *DOC: dissolved organic carbon, DON: dissolved organic nitrogen, LQ: limit of quantification (SM2) and n.d.: not determined.*

124 The first amendment used was an oxy-hydroxide sludge, called ochre, collected in a coal mine
 125 water treatment in the south of France, mainly composed of 2-6 μm particles. It contained 26.1
 126 % Fe, and had a pH value in water of 8.1 (measured according to ISO 10390 ; Thouin et al.,
 127 2019). A poorly crystalline goethite ($\text{FeO}(\text{OH})$) and aragonite (CaCO_3) were identified, and the
 128 presence of zincite (ZnO) was suspected (Mertz et al., 2021). The second amendment was cow
 129 manure, collected from a farm near Orléans (France). Its pH in water was 9.9 (according to ISO
 130 10390). The manure was dried at 30°C, ground in a mortar and sieved at 2 mm before using.
 131 The third amendment was biochar, produced from the slow pyrolysis at 500 °C of hardwood
 132 biomass (mixture of oak, beech, and hornbeam), followed by a sieving to obtain a particle size

133 between 0.5 and 1 mm (Norini et al., 2019). The pH in water was 9.5 measured (according to
134 ISO 10390) and the CEC of biochar (using the 0.05 N cobaltihexamine method) was 0.65
135 cmol.kg⁻¹. Chemical composition of amendments are detailed in Table 1.

136 *Agrostis capillaris* naturally present on the site was selected for this study. Nandillon et al.,
137 2019 showed that this indigenous *A. capillaris* is a metallicolous ecotype, more tolerant to the
138 stress condition of these mine tailings than a commercial non metallicolous ecotype. The seeds
139 of *A. capillaris* were directly sampled on the Pontgibaud mine site close to the tailings sampling
140 site.

141 **2.2 Pilot experiment**

142

143 *Figure 1. Design of the laboratory pilot experiment. (a); Analyses performed during the experiment (b) and experimental*
 144 *program presenting the chronology of the main events (c).*

145 The instrumented laboratory pilot device consisted of a closed stainless-steel column (100 cm
 146 in diameter and 145 cm high), placed in a temperature-regulated room at $23 \pm 1^\circ\text{C}$. The pilot
 147 design was previously described in Thouin et al. (2017). A layer of inert gravel (centimetric
 148 quartz) and a geotextile membrane were placed at the bottom of the column to facilitate outflow
 149 drainage without loss of tailing particles. This single metric pilot experiment (Fig. 1), represents

150 the up-scaling of the assisted phytostabilization method previously developed in multiple
151 microcosms (Thouin et al., 2019).

152 The column was filled with 814 kg (equivalent to 670 kg of dry weight (dw.)) of the < 2 cm
153 fraction of homogenized mine tailings (SM1b), and was equipped during the process at three
154 levels (Lv2: 26.2 cm, Lv3: 43.7 cm, and Lv4: 61.2 cm measured from the surface and after
155 solids settlement) with time domain reflectometry probes (TDR) (TRIME-PICO32, IMKO) to
156 measure moisture and temperature in tailings, and with inert Polytetrafluoroethylene/Quartz
157 porous probes (pore size 2 μm , three probes for each depth, regularly spaced) to sample pore
158 water. These probes were inserted into mine tailings at 30 cm from the column wall (Fig. 1a).
159 Five horticultural light-emitting diodes (LED) at the top of the column simulated 12-h day/night
160 cycles. Rainfall was simulated by a sprinkler system connected to a water reservoir and fed by
161 pumps, and consisted in the watering of 5.5 L of Mont Roucou[®] water each time and three
162 times a week. This mineral water was used because of its chemical composition close to that of
163 rainwater (pH = 6.38, electrical conductivity = 160 $\mu\text{S}\cdot\text{cm}^{-1}$, $\text{Cl}^- = 56 \mu\text{M}$, $\text{NO}_3^- = 24 \mu\text{M}$, SO_4^{2-}
164 $= 16 \mu\text{M}$, $\text{Na}^+ = 109 \mu\text{M}$, $\text{K}^+ = 7.7 \mu\text{M}$, $\text{Ca}^{2+} = 25 \mu\text{M}$, $\text{Mg}^{2+} = 21 \mu\text{M}$).

165 After three months of stabilization, the tailings settled by 12.5 % in height, and the thickness of
166 the tailings in the column reached a constant value of 68 cm. The first experimental step
167 corresponded to the control non-phytostabilized condition, which lasted 6 months ($t_{-6\text{m}}$ to $t_{0\text{m}}$).
168 Both levels Lv4 and Lv3 were always in the saturated part of the column all along the
169 experiment, whereas the Lv2 level was located in the unsaturated zone. The leachate was
170 collected in a steel tank at the bottom, noted Lch, and quantified using scales. This outflow
171 weight as well as moisture and temperature at the three levels (Lv2, Lv3 and Lv4) were
172 continuously monitored.

173 After 6 months (t_{0m} , corresponding to 167 days after starting the monitoring of the experiment,
174 Fig. 1c), 19 cm of tailings surface were stripped (195 kg, equivalent to 173 kg of dw.), and
175 amended with 1 wt% ochre, 1 wt% cow manure and 1 wt% biochar (i.e. 1.73 kg of each
176 amendment), homogenized, then replaced at the top of the column (SM1c). This tailing
177 amended level (Lv1) was instrumented with one TDR and three porous probes at 9.5 cm from
178 the surface, regularly spaced. The amendment was followed by the seeding of 4.1 g of *A.*
179 *capillaris* on all the tailings surface.

180 Sampling of pore water from levels Lv1, Lv2, Lv3, Lv4 and Lch was performed (before water
181 sprinkling) via fluorinated ethylene propylene (FEP) tubing connected to a peristaltic pump.
182 The 3 water samples from the 3 independent regularly spaced porous probes of each level (Lv1,
183 Lv2, Lv3 and Lv4) were pooled before determination of physicochemical and geochemical
184 parameters. In Lv1, water sampling was limited due to the low water contents and to the
185 competition with *A. capillaris* roots, this is why there were no water analyses after 231 days.

186 Solid sampling was performed in the column by coring at t_{-6m} , t_{0m} , t_{3m} and t_{11m} (at t_{0m} sampling
187 was performed before amendment). Coring was performed with 5 cm diameter and 1m length
188 stainless steel pipes. Only one coring was carried out at each experimental step, in order to
189 minimize disruptive effects. After sampling, the pipes were clogged and put back in place in
190 the tailings to fill the empty space. Each core was separated into four samples, Lv1 at a depth
191 of 0-19 cm, Lv2 at 19-34 cm, Lv3 at 34-51 cm, and Lv4 at 51-68 cm, corresponding to the pore
192 water sampling levels (Fig. 1c). These samples were homogenized, sub-sampled in sterile tubes
193 stored at -20°C for DNA extractions then stored at 5°C in tightly closed sterile jars for the
194 determination of functional diversity of microbial communities.

195 The sampling of *A. capillaris* biomass and rhizospheric and non-rhizospheric materials were
196 performed at t_{3m} , t_{6m} and t_{11m} , (respectively 92, 193 and 338 days after seeding). Five plastic
197 (polystyrene) tubes with an area of 19.6 cm^2 and a height of 7 cm were used to make small

198 cores of level Lv1. For each sampled *A. capillaris*, non-rhizospheric (Lv1 NR) tailings fraction
199 was separated from rhizospheric (Lv1 R) materials by shaking, and rhizospheric-associated
200 tailings particles were manually isolated from *A. capillaris* roots. The plants of *A. capillaris*
201 were washed with 0.5 mM CaCl₂ and deionized water and plant biomass was measured after
202 plant drying at 60°C during 48h (roots and leaves separately). The total plant cover of the
203 tailings surface was estimated by eye in percentage and was used to extrapolate the total
204 biomass of *A. capillaris* defined in gram of dry leaves and roots by m². At t_{3m} and t_{6m}, the *A.*
205 *capillaris* plants were cut at about 5 cm above the tailings' surface to simulate mowing and
206 leaves were recovered.

207 **2.3 Water analyses**

208 Electrical conductivity (EC), redox potential (Eh), pH, dissolved oxygen (DO), and temperature
209 of interstitial water were measured with a benchtop meter (multiparameter analyser C3040,
210 Consort) connected to an ORP sensor (platinum electrode, with an Ag/AgCl reference
211 electrode, 3M KCl, Eh value refers to the normal hydrogen electrode (NHE)), oxygen probes
212 (Fisherbrand), pH electrode (Fisherbrand) and conductivity probe (Sentek) (Fig. 1b, SM2). As,
213 Pb and Ba were analyzed by oven atomic absorption spectroscopy (AAS)
214 (Varian AA220Z), and Zn and Fe by flame AAS (Varian AA22FS) (SM2).

215 **2.4 Analyses of solids**

216 **2.4.1 Mineralogy and chemical composition**

217 Solid samples were dried and ground to 70 µm in an agate mortar for X-ray diffraction (XRD)
218 and chemical analyses (SM2). XRD was performed using an INEL CPS120 diffractometer
219 equipped with a Co anode. Measurements of total carbon (C), hydrogen (H), nitrogen (N), and
220 sulfur (S) were obtained using an elemental flash pyrolyser analyzer (Flash 2000, Thermo
221 Fisher Scientific) (SM2). Total organic carbon (TOC) contents were determined by Rock-Eval
222 pyrolysis (Rock-Eval 6 Turbo, Vinci Technologies) (SM2). Elemental concentration

223 measurements of all solid samples were performed on high resolution inductively coupled
224 plasma mass spectrometry (HR-ICP-MS ; Thermo Element-XR, details in SM2) after complete
225 dissolution by hydrofluoric acid attack (HNO₃ 65%, HCl 37% and HF 40%) using a pressurized
226 closed-vessel microwave system (MARS 6, CEM).

227 **2.4.2 Optical and SEM-EDS observations**

228 Fresh tailings material sampled in Lv1 at the end of the experiment was observed with a
229 binocular magnifier Leica 2616 APO equipped with a photography and video device and
230 connected to a computer equipped with Leica Mycosystem software. Scanning electron
231 microscopy coupled with energy dispersive X-ray spectroscopy (SEM-EDS) observations were
232 performed on a TM 3000 (Hitachi) at 15 kV accelerating voltage. SEM was coupled to a
233 SwiftED3000 X-Stream module (Hitachi). The acquisition time of EDS point analyses was 300
234 seconds and 15 minutes for maps with a resolution of 512 x 384 pixels.

235 **2.4.3 DNA extraction and next generation sequencing**

236 Total nucleic acids were extracted in duplicate from 0.5 g (wet weight) of each solid sample
237 with a FastDNA® SPIN Kit for soil (MP Biomedicals, Illkirch, France). DNA was quantified
238 with the Promega Quantifluor®, using the Quantus™ fluorometer (Promega, France).

239 For next generation sequencing, a fragment of the gene coding 16S rRNA (bacteria and archaea)
240 was amplified using the barcoded, universal primer set (515WF/918WR) (Wang et al., 2009).
241 The primers used to amplify the specific fungal barcode ITS2 were w404 and w40 (Degois et
242 al., 2019). PCR reactions were performed using AccuStart II PCR ToughMix kit and cleaned
243 (HighPrep PCR beads, Mokascience). Pools were submitted for sequencing on Illumina MiSeq
244 instrument at GeT-PlaGe (Auzeville, France). The raw datasets are available on the European
245 Nucleotide Archive system under project accession number PRJEB52405 and PRJEB52412.

246 Sequences were processed using the FROGS (v.3.0) bioinformatics pipeline (Escudié et al.,
247 2017), implemented into the Genotoul platform of the Galaxy server of Toulouse. Fastq paired
248 reads were merged with FLASH software, and clustering into OTU with Swarm and an
249 aggregation distance clustering of 3. Chimera and operational taxonomic unit (OTU) with a
250 proportion less than 0.005 % of all sequences were removed. Taxonomic affiliation was
251 performed using BLASTn and the Silva 132 database for 16S rRNA sequences and the Unite
252 Fungi 8.0 database for ITS2 sequences. Filtration on taxonomic affiliation was done at
253 minimum identity of 100% and minimum coverage of 95%. The FROGS pipeline implemented
254 Phyloseq R package was used for OTU structure visualization, rarefaction curves, and alpha
255 diversity index calculations. Chao 1 index (non-parametric measurements) estimates the
256 number of unobserved species from those observed 1 or 2 times while the Shannon and
257 invSimpson diversity indexes give respectively a measure of heterogeneity of microbial
258 community and the probability that two randomly picked individuals do not belong to the same
259 species.

260 **2.4.4 Functional diversity of heterotroph microorganisms**

261 Biolog™ Ecoplates community-level substrate utilization assays were used to study the
262 functional diversity of microbial communities (Garland, 1999). The Biolog™ Ecoplates were
263 incubated at 25 °C and the absorbance values (optical density (OD) at 590 nm) were monitored
264 using an Omega SPECTROstar (BMG Labtech) microplate spectrophotometer at t=0 and 168
265 h (7 days). The well absorbance values were adjusted by subtracting the average absorbance of
266 the control well (water only) at t=0. After subtracting the control well, an OD_{590nm} > 0.25 was
267 considered as positive. Negative readings (OD < 0) were set to zero for all subsequent analyses.

268 **2.5 Statistical analysis**

269 Statistical analysis were performed using R (<http://www.r-project.org/>; version 4.3.0) with the
270 vegan package (version 2.5-7). To visualize differences in the OTUs-based community

271 composition, we performed an agglomerative hierarchical clustering (AHC) on the 100 most
272 abundant OTUs of 16S rRNA and ITS 2 sequencing data, using Bray-Curtis dissimilarity
273 metric, and Ward's minimum variance. Redundance analysis (RDA) was performed to identify
274 the relationships among samples, environmental variables, and relative abundance of phyla.
275 This analysis was calculated based on Hellinger - transformed phylum abundance basis of 16S
276 rRNA and ITS 2 data (Borcard et al., 2011). Environmental explanatory tested variables were
277 as follows: humidity, pH, TOC, [S], [N], [Fe], [Pb], [Zn], [As], [Cu], [Ba] (solid concentrations
278 at t_{0m} , t_{3m} , t_{11m}) and were standardized. The function ordistep in vegan package was used to
279 identify the significant explanatory forward environmental variable. The significance of the
280 RDA model was tested by ANOVA based on Monte Carlo test with 999 permutations. This
281 analysis helps to determine the most influential factors and the extent that various
282 environmental parameters affected microbial composition.

283 **3 Results**

284 **3.1 Percolated water composition**

285 **3.1.1 Physico-chemical parameters**

286 Pore-waters in the subsurface levels of the column (Lv2, Lv3, and Lv4) were characterized by
287 constant pH values between 4 and 3, whether before or after the amendment (Fig. 2). In Lch,
288 the pH was higher but decreased from 6 to 4 after amendment of the tailings. In Lv1, the pore
289 water pH was higher than in Lv2, Lv3, and Lv4. Values of redox potential was positive (>300
290 mV NHE) before amendment, even in the saturated levels (Fig. 2). After amendment, Eh NHE
291 increased in all sampling level and remained positive during the experiment.

292

293 *Figure 2. Evolution of water pH, Eh NHE, Pb, Zn and Ba concentrations in water all along the pilot experiment. Lv1 to Lv4*
 294 *represent the sampling depths in the tailings. Lv1 was amended and seeded at t_{0m}. Lch was the outlet of the pilot.*

295

296

297 **3.1.2 Metal(loid)s concentrations**

298 Pb was the metal with the highest concentration in tailings' water and leachate. Before t_{0m} , Pb
299 concentrations were similar and constant in Lv2, Lv3, and Lv4 with values of 14.4 mg.L^{-1} (Fig.
300 2). In Lch, Pb concentrations were lower and increased to reach 2.3 mg.L^{-1} just before the
301 amendment. In the amended level Lv1, mean Pb concentration was $532 \pm 77 \text{ } \mu\text{g.L}^{-1}$. In Lv2 and
302 Lv3, Pb rapidly decreased after the amendment to values close to 3 300 and 4 000 $\mu\text{g.L}^{-1}$
303 (respectively), then between t_{3m} and t_{11m} , Pb slightly increased to reach 8 160 and 7 150 $\mu\text{g.L}^{-1}$
304 at the end of the experiment. At the bottom of the column, in Lv4, Pb concentration rapidly
305 increased after the amendment to reach a maximum of 88 900 $\mu\text{g.L}^{-1}$ on day (d) 207 then
306 decreased down to 4 100 $\mu\text{g.L}^{-1}$ on d 319. As for Lv4, Pb concentration in Lch increased after
307 the amendment to reach a maximum of 14 775 $\mu\text{g.L}^{-1}$ at d 214 and then decreased down to 3
308 700 $\mu\text{g.L}^{-1}$ at t_{11m} .

309 During the period before the amendment, Ba concentrations were between 8.2 and 18 $\mu\text{g.L}^{-1}$ in
310 Lv2, Lv3 and Lv4, and between 101 and 65 $\mu\text{g.L}^{-1}$ in Lch (Fig. 2). After t_{0m} , Ba concentration
311 rapidly decreased below 2 $\mu\text{g.L}^{-1}$ in Lv2 and Lv3, while in Lv4 it increased to a maximum of
312 77.6 $\mu\text{g.L}^{-1}$ on d 207 and decreased under 2 $\mu\text{g.L}^{-1}$ on d 300. Between d 300 and the end of the
313 experiment, Ba concentration in Lv2, Lv3 and Lv4 slowly increased to about 10 $\mu\text{g.L}^{-1}$. In Lch,
314 two peaks were observed after the amendment, at 207 days (145.6 $\mu\text{g.L}^{-1}$) and at 252 (51.4
315 $\mu\text{g.L}^{-1}$).

316 As concentrations in pore water in Lv2, Lv3 and Lv4 were less than 15 $\mu\text{g.L}^{-1}$ throughout the
317 experiment (SM3). In Lch, As concentration decreased from 233 to 13 $\mu\text{g.L}^{-1}$ between t_{6m} and
318 t_{0m} . After the amendment As decreased below 5 $\mu\text{g.L}^{-1}$ and then increased at the end of
319 experiment to reach 26.7 $\mu\text{g.L}^{-1}$.

320

321 **3.2 Evolution of the solids**

322 The evolution of parameters related to organic matter and the main contaminants in solids is
 323 presented in Table 2. Amendment slightly increased the concentration in carbon (total C, TOC)
 324 in Lv1 and in Lv2, but not at all in the deeper levels Lv3 and Lv4. The other analysed elements
 325 did not vary according to experimental time and depth of layer in the column. In particular, Pb,
 326 the main contaminant, did not exhibit significant trends as a function of depth and time. One
 327 can only note slightly lower Pb contents in the rhizospheric area compared to the non-
 328 rhizospheric one. Zn contents slightly increased in the upper levels (Lv1 and Lv2) just after the
 329 addition of amendments (t_{3m}), due to the presence of Zn in ochre, then returned to values close
 330 to that of the tailings.

331 X-ray diffractograms of the tailings sampled at different depths (Lv1, Lv2, Lv3, and Lv4) at
 332 the end of the pilot experiment revealed no change of the mineralogy (SM4): quartz, orthoclase,
 333 anglesite, beudantite and a phyllosilicate (presumably muscovite) were the main crystalline
 334 phases, as previously identified in the initial tailings (Mertz et al., 2021).

335 *Table 2 Concentrations of the main interesting constituents in the solids sampled in four depths and at different periods of the*
 336 *pilot experiment, and analyzed by ^a Flash pyrolyzer analyzer, ^b Rock-Eval 6 and ^c HR-ICP-MS.*

337 Initial tailing composition is available in table 1. TOC: total organic carbon, Lv1 to Lv4 represent the sampling depths in the
338 tailings. Lv1 R: solid sampled in the rhizospheric zone, Lv1 NR: solid sampled in the non rhizospheric zone, t_{0m}: 6 months after
339 the beginning of the monitoring without amendments and plants, t_{3m}: 3 months after adding amendments and seeding *Agrostis*
340 *capillaris*, t_{11m}: end of the experiment, 11 months after adding amendments and seeding *A. capillaris*, and n.d.: not determined.

341

342 3.3 *Agrostis capillaris* development

343 Three months after seeding (t_{3m}), thin leaves of *Agrostis capillaris* have grown and a dense
344 implantation with about 80% of surface cover was observed (Table 3). The biomass was about
345 190 g.m² for leaves and stems and 57 g.m² for roots. At t_{3m}, *A. capillaris* was cut, and 3 months
346 later, a reduced plant cover (50%) was observed but with larger and better developed leaves.
347 Root biomass has also increased between t_{3m} and t_{6m}. A second cut was made at t_{6m}. At the end
348 of the pilot experiment, 11 months after seeding, the biomass of aerial parts was multiplied by
349 four (SM1d). *A. capillaris* with stolon was observed and plant cover increased between t_{6m} and
350 t_{11m}. Measured root biomass seemed to drastically decrease, but only roots in the first 7
351 centimeters were weighted whereas roots had colonized the entire thickness of the amended
352 level and were observed up to 40 cm deep.

353 *Table 3 Agrostis capillaris* development. Plant cover was estimated visually and the biomass was measured for a determined
 354 surface where the *A. capillaris* plants were well developed. The extrapolated biomass was determined with biomass and plant
 355 cover. * Root biomass was determined only in the first 7 cm.

	Plant cover (%)	Biomass sampling		Extrapolated biomass	
		Aerial Parts (g)	Roots* (g)	Aerial Parts (g.m ²)	Roots* (g.m ²)
t _{3m}	80	2.4	0.7	191.5	57.0
t _{6m}	50	2.4	1.2	119.7	73.3
t _{11m}	70	9.8	0.2	700.9	11.4

356 *t_{3m}, t_{6m}, t_{11m}*: respectively 3 months, 6 months and 11 months after adding amendments and seeding *A. capillaris*.

357 **3.4 Tailings stabilization by *Agrostis capillaris* root system**

358 The surface of the tailings at the end of the pilot experiment was visually invaded by the
 359 *Agrostis capillaris* root system. The binocular magnifier enabled to observe solid particles
 360 forming immobilized tailing aggregates associated with the roots (Fig. 3a). Some fragments of
 361 roots observed with SEM-EDS presented fibrous coverage (Fig. 3b) enriched in P and Pb (Fig.
 362 3c point 1) compared with the simple solid particles present at the root surface (Fig. 3c point
 363 2). Fine filaments of 3-4 μm diameter were observed in the rhizosphere (Fig. 3d, e and f). They
 364 might be fungal hyphae. EDS mapping revealed the presence of Fe and Pb on their surface and
 365 inside their membrane (Fig. 3e point 1, and f).

366

372

373 3.5 Microbial diversity and structure

374 3.5.1 Community species richness and diversity

375 After treatment steps, a total of 790 820 16S and 920 302 ITS 2 sequences were obtained from
 376 the 19 samples. The rarefaction curves reach a plateau for all samples showing that the diversity
 377 of communities was well sampled (SM5). The richness of 16S OTUs was homogeneous before
 378 amendment at t_{-6m} and t_{0m}, with values varying between 431 in Lv3 t_{-6m} and 752 in Lv4 t_{0m}.
 379 After amendment, an increase of richness was observed except in Lv4 t_{11m}. Chao1 index shows

380 that the majority of OTUs was sequenced (Table 4). The richness of ITS2 sequences was lower
 381 than 16S sequences. As with bacteria, the number of OTUs increased after amendment in all
 382 levels except in the deepest level at the end of the experiment. The bacterial species diversity,
 383 based on the Shannon and InvSimpson indexes (Table 4) increased after amendment in the
 384 surface levels Lv1. In Lv2 and Lv3 an increase of diversity indexes was also observed at t_{3m}
 385 and t_{11m} . The lowest Shannon and InvSimpson indexes were observed in Lv4 at t_{11m} . For the
 386 fungi, the evolution of Shannon and InvSimpson indexes were less obviously related to the
 387 experimental conditions.

388 *Table 4: 16S and ITS 2 sequences diversities estimation of the solids sampled in four depths and at different periods of the pilot*

395 3.5.2 Microbial community structure

396 Samples of solids from the pilot experiment hosted bacterial and fungal communities presenting
397 different spatial and temporal distributions (Fig. 4). The 100 most represented phyla of
398 procaryotes (Fig. 4A) included Proteobacteria, Acidobacteria, Chloroflexi, Bacteroidetes,
399 Gemmatimonadetes, Actinobacteriaceae, Planctomycetes, Cyanobacteria, Firmicutes,
400 members of the Deinococcus-Thermus group for the bacteria, then Thaumarchaeota and
401 Euryarchaeota for the archaea. The AHC analysis, that groups the OTUs according to
402 similarities of occurrence in samples, shows a cluster of OTUs, gathered in the upper part of
403 the Fig. 4A, that were mainly present in the tailings before amendment (t_{-6m} and t_0) and in the
404 deepest levels of the column (Lv3 and Lv4) all along the experiment (OTUs n°9 to n°96). The
405 ten most abundant procaryote OTUs (in bold) were present in this group that included
406 Acidobacteria, Chloroflexi, Proteobacteria and Thaumarchaeota, however none of them was
407 identified at the genus level (SM6). Procaryote OTUs more represented in surface levels from
408 t_{3m} to t_{11m} , and influenced by the amendment and plant growth, are grouped in three clusters in
409 the bottom part of Fig. 4A. The cumulative list of the ten most represented known bacterial
410 genera in each sample (SM7), included three sulfur-oxidizing bacteria, namely *Sulfuriferula*,
411 *Sulfurifustis* and *Thiomonas*, and two autotrophic Fe-oxidizing bacteria, i.e. *Gallionella* (only
412 in Lv4 at t_{3m}) and *Sideroxydans* (only in Lv4 at t_{11m}). All the 44 other major genera are
413 heterotrophic organisms. A known nitrogen fixing genus, *Mesorhizobium*, was present in the
414 list of the 10 most represented procaryote OTUs in Lv1, both in the rhizospheric and non
415 rhizospheric samples. The contribution of the 3 sulfur-oxidizing bacteria, expressed as the sum
416 of their relative abundance in the 10 most abundant identified genera (SM8 and SM9), shows
417 their preponderance in the initial tailings. Their relative abundance strongly decreased in Lv1,
418 Lv2 and Lv3 at t_{3m} . At the end of experiment their contribution rose in Lv3 and Lv4.

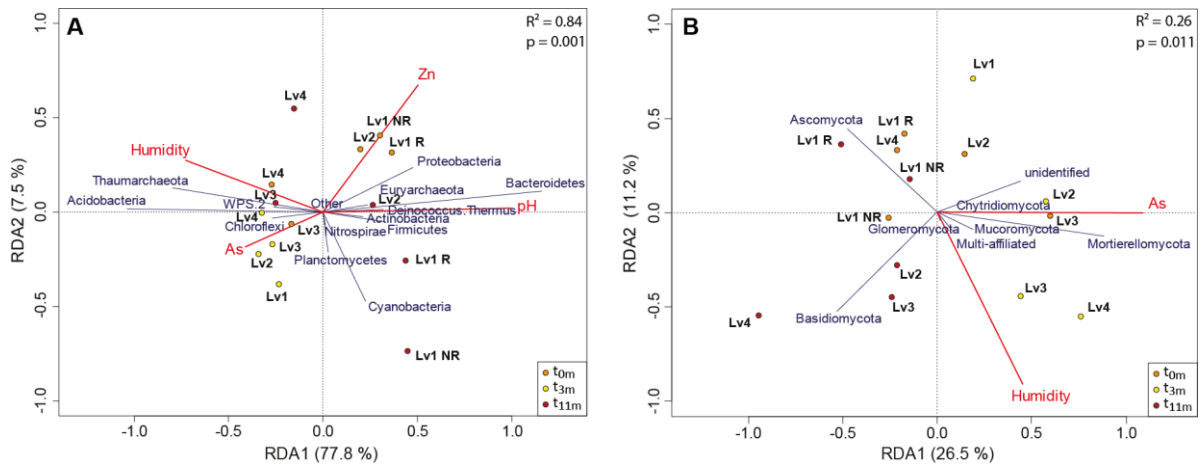

420
 421 Figure 4. AHC analysis of the 100 most abundant OTUs (10 most abundant in bold) in solid samples from the pilot experiment.
 422 A: bacteria and archaea (based on 16S sequences), B: fungi (based on ITS sequences) (Lv1 to Lv4 represent the sampling
 423 depths in the tailings, Am: tailings amended with 1 wt% ochre, 1 wt% cow manure and 1 wt% biochar, Lv1 R: solid sampled
 424 in the rhizospheric zone, Lv1 NR: solid sampled in the non rhizospheric zone, t-6m: start of the experiment, t0m: 6 months after
 425 the beginning of the monitoring without amendments and plants, t3m: 3 months after adding amendments and seeding *Agrostis*
 426 *capillaris*, t11m: end of the experiment, 11 months after adding amendments and seeding *A. capillaris*).

427 The distribution of the 100 most abundant fungal OTUs (Fig. 4B) shows some tendencies
 428 already observed with bacterial OTUs, such as a group of fungal OTUs mainly found in the
 429 initial tailings, at t-6m in all levels, and t0m from Lv2 to Lv4 gathered at the top of Fig. 4B.

430 Another group of OTUs was mainly found in the surface levels after amendment (bottom of
431 Fig. 4B). The 10 most abundant fungal OTUs were distributed between these two groups (Fig.
432 4B, SM10). A group of fungal OTUs (OTU 14 to OTU 93), probably resulting from the
433 amendment, was found at t_{3m} and t_{11m} in deeper levels (up to Lv3 at t_{11m}). The fungi present in
434 the rhizospheric materials at t_{3m} and t_{11m} are different from those found in non rhizospheric Lv1
435 samples. The classification of the ten most represented known fungal genera (SM11) shows
436 that the genera *Mortierella* and *Talaromyces* were strongly represented in the original tailings
437 (t_{-6m}) and detected in all samples. The genera *Clonostachys*, *Coniochaeta* and *Pisolithus* were
438 found among the 12 dominant fungal genera at t_{-6m} . The most represented genus in the freshly
439 amended Am Lv1 was *Remersonia*. The genera *Zopfiella* and *Mortierella* were also found in
440 this sample, in small proportions. At t_{3m} , the genera *Mortierella*, *Clonostachys* and *Zopfiella*
441 were still present. The genus *Podospora* was present in all levels at this sampling time, , together
442 with *Giberella*, emerging t in Lv1 R and Lv4. The fungal diversity of the rhizospheric Lv1 at
443 t_{3m} differed from that of the other levels, in particular because it was the only level containing
444 *Saccharomyces* as one of the 10 dominant fungal genera. At t_{11m} , *Podospora* represented nearly
445 50% of the fungal genera present in Lv1 R andLv4 exclusively included *Malassezia* as a
446 dominant fungal genera.

447 A RDA was performed to identify the influence on microbial community structure of 12
448 physico-chemical characteristics of solid phases (Fig. 5). For Bacteria and Archaea (Fig. 5A)
449 the results indicated that pH, humidity, Zn, and As were explanatory variables that significantly
450 influenced the community structure, which explained 88.6 % ($p = 0.001$) of the total variance.
451 In particular, the highest pH and lowest water content seemed to favour the presence of
452 Bacteroidetes and Proteobacteria, whereas low pH and high water saturation seemed to induce
453 higher proportions of Acidobacteria and Thaumarchaeota. Zn and As concentrations in the
454 solids exerted antagonist influences. For Fungi (Fig. 5B), As and humidity were the only

455 significant explanatory variables that influenced the community structure. These parameters
 456 significantly explain ($p = 0.011$) 37.7 % of the total variance of fungal community structure.
 457 High As concentrations seemed to favorise the development of Mortierellomycota while low
 458 water content favoredised the presence of Ascomycota.

459

 465 *adding amendments and seeding *Agrostis capillaris*, t_{11m}: end of the experiment, 11 months after adding amendments and*
 466 *seeding *A. capillaris*).*

467 3.5.3 Functional diversity of heterotrophic microorganisms

468 The substrate spectrum of active cultivable heterotrophs was mainly driven by polymers and
 469 carbohydrate degradation in the initial tailings (Fig. 6). Amended surface level clearly displayed
 470 higher heterotrophic activities and a deployment of polymer and carboxylic acids degradation
 471 was observed at t_{0m}. Increase of carboxylic acids biodegradation activities was shared by all
 472 levels at t_{3m}. A large spectrum of heterotrophic activities was detectable in non-rhizospheric
 473 compartments Lv1, Lv2 and Lv3 at t_{11m}, when heterotrophic activity was lower in the
 474 rhizospheric samples, and nearly inexistent in the deepest level Lv4.

475

476

477 *Figure 6. Functional diversity of cultivable heterotroph microorganisms in solid samples from the pilot experiment (Lv1 to Lv4*

482 4 Discussion

483 4.1 Stabilization of Pb linked to the development of *Agrostis capillaris*

484 The *Agrostis capillaris* plants grown for 11 months in the column developed an abundant root
 485 system that macroscopically retained tailing particles. *A. capillaris* was already reported as a
 486 good candidate for phytostabilization, often present as a pioneer plant of polluted sites, resistant
 487 to metals and metalloids including Pb and As (Bradshaw, 1952; Meharg and Macnair, 1991;
 488 Ernst, 2006; Nandillon et al., 2019). *A. capillaris* has been found to grow spontaneously on
 489 contaminated soils, and was recognized as an interesting candidate for the phytostabilization of
 490 As and Pb polluted sites (Austry et al., 2013; Rodriguez-Sejjo et al., 2016). When using pioneer
 491 plants for phytostabilization purposes, preference should be given to pseudo-metallophyte over
 492 hyperaccumulator species to minimize the mobilization of metals (Houben et al., 2013). Lead-
 493 rich minerals associated with roots of our *A. capillaris* plants were observed by SEM-EDS, co-
 494 occurring with high either iron or phosphate concentrations. Pyromorphite (Pb₅(PO₄)₃(C1) or
 495 (OH)⁻ grains have been observed in the outer roots' cell-walls of *A. capillaris* grown in a mine

496 waste contaminated soil (Cotter-Howells et al., 1999). The authors suggested that the
497 precipitation of Pb phosphate might be related to a mechanism of resistance. As a fact,
498 Nandillon et al. (2019) found higher Pb concentrations in roots of this metallicolous ecotype of
499 *A. capillaris* than in a non-metallicolous one, grown on Pontgibaud tailings, suggesting that Pb
500 immobilization in roots might increase the resistance of plants to this toxic element. Apoplastic
501 sequestration of chloropyromorphite was observed by transmission electron microscopy (TEM)
502 in roots of Pb-resistant *Brachiaria decumbens* (Kopittke et al., 2008).

503 **4.2 Impact of phytostabilization on water and solids composition**

504 Amendment of the tailings surface layer was performed to facilitate phytostabilization through
505 the development of *A. capillaris*. This event induced a local increase of solids and pore water
506 pH, accompanied with a decrease of Pb concentration in pore water. This phenomenon, in
507 agreement with results of microcosm experiments (Thouin et al., 2019), was more pronounced
508 in the planted layer, and its amplitude decreased with depth. In the water saturated deeper level
509 Lv4, conversely, a sharp peak of Pb concentration in pore water was observed at the beginning
510 of the phytostabilization process. This phenomenon might be linked to different processes.
511 First, amendment brought several soluble salts releasing cations (Ca^{2+} , Na^+ , Mg^{2+} ...) that could
512 compete with Pb^{2+} for adsorption on mineral surfaces (Li et al., 2012). This competition might
513 have been compensated by the pH increase in the surface layers, but not in the deeper layer
514 whose pH was not influenced. Another phenomenon that could explain Pb release in Lv4 might
515 be a slight pH decrease linked with the production of CO_2 by the organic matter (manure)
516 degradation. This phenomenon was observed at microcosm scale (Thouin et al., 2019) and the
517 associated Pb mobilization was numerically simulated (Mertz et al., 2021). Again, this
518 acidification might have been negligible in the upper levels because of the buffering effect of
519 the amendment, that were not efficient in Lv4.

520 The redox potential in sampled water never decreased significantly, suggesting that reducing
521 processes, such as ferric iron or sulfate bio-reduction, did not establish at a macroscopic scale,
522 whereas they might have occurred locally in micro-environments.

523 Interestingly, Ba behaved in the same way as Pb with a peak of concentration in Lv4 observed
524 following the amendment and seeding. Yet, both Ba and Pb form low-solubility solid phases
525 with sulfate (PbSO_4 and BaSO_4). In a previous pot experiment (Norini et al., 2019) correlations
526 between Ba and major ions concentrations were highlighted. This could suggest that soluble
527 ions derived from amendment (and more precisely from biochar) induced an increase of Ba
528 concentration in pore water. Zinc release was also observed in all levels except the surface. This
529 might be related both with the transport of Zn-containing ochre in the underlying acidic layers,
530 inducing release of Zn from this amendment, and/or with the release of Zn from the tailings due
531 to competition for adsorption sites with the salts released by amendment (Voegelin et al., 2001).

532 **4.3 Impact of phytostabilization on microbial communities**

533 The development of a plant cover during phytostabilization of mine tailings is generally
534 associated with a diversification of microbial communities in the colonized surface material.
535 This shift can be associated with the amendments provided to help plant growth (Valentin-
536 Vargas et al., 2014), however survey of long-term phytostabilized mine tailings shows that
537 plants alone can induce a complexification of the microbial communities' structure
538 (Asemaninejad et al., 2020). The observed evolutions linked with phytostabilization of mine
539 tailings include the increase of the proportion of heterotrophic bacteria linked to a decrease of
540 the abundance of chemo-autotrophic or mixotrophic bacteria involved in iron and sulfur cycles
541 (Mendez et al., 2007; Valentin-Vargas et al., 2014; Gil-Loaiza et al., 2016; Li et al., 2015), and
542 the development of nitrogen-fixing and plant growth promoting bacteria (Honeker et al., 2019;
543 Asemaninejad et al., 2020). Our moderately acid tailings hosted three main sulfur oxidizers, i.e.
544 *Sulfuriferula*, *Sulfurifustis* and *Thiomonas*, and no FeII-oxidizing acidophiles, whereas many

545 previous studies reported the occurrence of the genera *Leptospirillum*, *Acidithiobacillus*,
546 *Alicyclobacillus*, *Sulfobacillus*, or *Ferrithrix* (Li et al., 2016; Li et al., 2017; Honeker et al.,
547 2019; Asemaninejad et al., 2020). *Sulfuriferula* genus includes the species *Sulfuriferula*
548 *plumbophilus*, formerly *Thiobacillus plumbophilus*, a chemolithotrophic bacterium growing
549 between pH 4.0 and pH 6.5 by oxidation of galena, producing anglesite (Drobner et al., 1992).
550 *Sulfurifustis* genus (Kojima et al., 2015) gathers autotrophic species oxidizing reduced sulfur
551 compounds (thiosulfate, tetrathionate, elemental sulfur) at near neutral pH conditions.
552 *Thiomonas* species are acid-tolerant mixotrophic organisms presenting optimal growth in
553 presence of both organic substrates and sulfur compounds or arsenite (Battaglia-Brunet et al.,
554 2011). The main Pb minerals identified by XRD in Pontgibaud tailings were the oxidized forms
555 anglesite and beudantite. However, a minor fraction of Pb probably remained in the form of the
556 sulfide galena. As a fact, a darker zone that was sampled from the tailing was enriched in Pb,
557 suggesting the presence of less oxidized materials. The absence of acidophilic iron-oxidizing
558 bacteria, that distinguishes our system from many other described autotrophic microbial
559 communities of tailings, may be explained by the low proportion of Fe-bearing sulfides (pyrite
560 and arsenopyrite) compared with galena. Amendment with material providing organic
561 substrates and neutralizing acidity had an immediate effect on microbial communities'
562 composition in the surface level, as previously observed (Valentin-Vargas et al., 2014), with an
563 increase of the proportion of heterotrophic phyla and an activation of the metabolism of organic
564 substrates, in terms of activities and diversity. Moreover, our pilot experiment highlighted the
565 effect of amendments in the underlying zones, with clear changes of global community
566 composition in the non-saturated zone below roots. The two deeper saturated levels were less
567 influenced in terms of global bacterial diversity, however the proportion of sulfur-oxidizers in
568 the 10 most abundant OTUs declined both in Lv2 (non-saturated) and Lv3 (saturated just below)
569 3 months after the amendment and seeding event. Only the deepest level Lv4 always kept a

570 significant proportion of sulfur-oxidizers. However, at t_{11m} , the proportion of sulfur-oxidizers
571 was restored in Lv3, suggesting an attenuation of the organic substrates supply from the surface.
572 Honeker et al. (2019) already observed re-acidification of phytostabilized mine tailings during
573 phytostabilization, in the initially amended surface levels. Here, we showed a transient
574 influence of surface amendments and plant growth on the underlying levels, however limited
575 spatially as the deeper saturated zone retained the characteristics of initial tailings. From the
576 perspective of Fe cycling, the typical acidophile FeII-oxidizers *Leptospirillum* were not
577 represented in the 100 most abundant OTUs, neither in the 10 most abundant identified genera,
578 however they were detected by the sequencing as minor OTUs typically present in the tailings
579 signature (t_{6m} and Lv3-Lv4). Two other less acidophile chemolithotrophic FeII-oxidizers,
580 *Gallionella* and *Sideroxydans*, emerged (list of 10 most abundant identified genera) in the
581 deepest level Lv4 at t_{3m} and t_{11m} . In parallel, the presence of an acidophilic FeIII-reducer,
582 *Acidibacter*, was noticed (list of 10 most abundant identified genera) in Lv3 at t_{3m} and Lv1R at
583 t_{11m} . *Acidibacter* was previously mentioned as part of the acid-generating group in
584 phytostabilized pyritic mine tailings (Honeker et al., 2019). Its presence in our column suggests
585 that amendments and plant growth could induce activation of Fe cycling, including FeIII-
586 reduction in the surface levels fueled by new organic electron donors, providing energy (FeII)
587 for moderately acidophilic FeII-oxidizers in the deepest zones.

588 In the surface level colonized by plants, plant growth promoted bacteria of the genus
589 *Mesorhizobium* which emerged in the 10 most abundant OTUs at t_{11m} , suggesting that
590 conditions favorable to long-term plant maintenance were established, and that N₂-fixing
591 bacteria could take over from the manure as a source of nitrogen necessary for plant
592 development. Asemaninejad et al. (2020) already observed groups of N₂-fixing bacteria
593 including *Mesorhizobium* in long-term vegetated tailings. Bacterial diversity of rhizospheric
594 and non rhizospheric materials did not differ significantly, and evolved similarly from t_{3m} to

595 t_{11m} , both in terms of global diversity and representation of the major known bacteria. According
596 to Honeker et al. (2019), the microbial diversity in a phytostabilized soil can be similar in the
597 rhizospheric and bulk soils when pH is near neutral; differences appear when the pH is acidic
598 (<4). In our case, amendment enabled to maintain pH >4 in Lv1 along the experiment. However,
599 differences in the metabolism of organic compounds were observed at t_{11m} , the metabolic
600 activity being higher in the bulk than in the rhizospheric material. Whereas root exudates should
601 feed the heterotrophic microbes (Navarro-Noya et al., 2010), here, not the organic substrate
602 availability but other type of limitation of microbial activity might be linked to rhizospheric
603 processes. In particular, phosphate might be depleted in the root vicinity, because of uptake by
604 plants. In a context of low phosphate bioavailability linked to low solubility of Pb phosphate,
605 competition between plants and microbes for this essential nutrient might occur.

606 Concerning fungi, about 90 species of *Mortierella* are known mainly from soil, the rhizosphere,
607 and plant or animal remains in contact with soil (Domsch et al., 1980). Members of *Mortierella*
608 (phylum Zygomycota) are rapidly growing organisms which have been suggested to be
609 saprobes in forest ecosystems (Heitefuss, 2011) and that are important decomposers in soil. The
610 genus *Mortierella* also comprises highly chitinolytic fungi. Due to their potentially endophytic
611 trophic lifestyle, *Mortierella* may be tracking changes in nutrients driven by vegetation turnover
612 (Veach et al., 2017). It is therefore not surprising that this fungal genus was found in the initial
613 tailings that were surrounded by a forest. The adaptive capacities and oligotrophic lifestyle
614 allowed these fungi to be present throughout the experiment. *Talaromyces* are saprotrophic
615 Ascomyceta which contribute to the spoilage of dead or decaying organic material. They are
616 notoriously tolerant to extreme conditions. *Talaromyces* species are commonly distributed in a
617 wide range of substrates, mostly in soil. In an As-contaminated mine soil, Nam et al. (2019)
618 showed that a fungal strain hyper-tolerant to arsenic of *Talaromyces* sp. efficiently removed As
619 from aqueous medium (>70%) with significant improvement by the surface modification of the

620 fungi with Fe(III) (hydr)oxides. Thus, the hypothesis of a contribution of fungal biomass to the
621 removal of As and/or metals from the pore water of our system cannot be excluded, as our
622 SEM-EDS observations suggested the presence of Fe and Pb at the surface of fungal hyphae.
623 *Pisolithus* is a genus of fungi within the family *Sclerodermataceae*. It is an ectomycorrhizal
624 (ECM) *Gasteromycetes* able to realize symbiosis with various trees (Cairney et al., 2013). We
625 found this genus in Lv1 t_{0m} , in the amended level, but also in Lv4 at t_{0m} , thus it was not
626 exclusively present in the amendments. This genus was detected in different levels and at
627 different times thereafter. The spores of this ectomycorrhizal fungus were probably initially
628 present in the tailings and were maintained throughout the experiment thanks to their great
629 resistance.

630 **5 Conclusion**

631 The first objective of phytostabilization is the decrease of pollutants spreading through surface
632 water runoff and wind erosion. However, the modification of the transfer of metals and
633 metalloids linked with infiltration processes may have important implications in terms of impact
634 on downstream groundwater quality or mine drainage. Here, the phytostabilization technology
635 was examined not only in the surface zones but also from the perspective of the evolution of
636 underlying compartments. The metallicolous *A. capillaris* grew and efficiently trapped tailing
637 particles in its root system. The most mobile pollutant, i.e. lead, was actually stabilized in the
638 surface tailings layer. Beyond these phenomena previously reported for planted tailing systems,
639 our pilot experiment revealed some phenomena occurring in the underlying zones, following
640 the amendment/seeding event, such as a transient increase of the pore water concentrations in
641 Pb, Zn, and Ba. Geochemical data acquired at this laboratory pilot scale will find application in
642 the development of numerical model, helpful to foresee the future evolution of pollutant fluxes
643 in the waste heap. Meanwhile, the phytomanagement process strongly influenced the microbial
644 diversity and metabolic activity in the surface layer but less intensely in the deeper ones. The

645 main parameters influencing bacterial communities' structure, namely pH and water saturation
646 could be easily related to amendment in the surface compartment, and to the experimental
647 simulation of a groundwater zone. The evolution of fungal community and their potential
648 influence on metalloids and metals dynamics would deserve deeper investigation. Thus, the
649 overall influence of a phytomanagement strategy should be considered and evaluated not only
650 in the surface compartments, but also considering the potential diffusion of phytostabilization-
651 related substances that could influence both abiotic phenomena and microbial processes, toward
652 underlying non-saturated and saturated zones of the mining site.
