minerals.

9 Abstract

10 The Chenaillet ophiolite, South of Montgenèvre (France), represents a preserved portion of the alpine ocean. The gabbros form lenticular bodies 50 to 200 m thick and a few hundreds of meters 11 12 wide. They are intrusive in the serpentinites and often overlain by pillow-lavas. Plagiogranite/albitite 13 veins are rare and volumetrically negligible. The petrology of the gabbro s.s. show great details of the 14 progressive cooling of the massif, clinopyroxene are often rimmed by brown to green amphibole +/-15 ilmenite/titanite. Thermometry on these amphibole assemblages indicates a retrograde temperature 16 evolution from late magmatic to subsolidus, between 950-900°C, 800-750°C, 600-500°C. In a shear zone, a string of titanite associated with monazite and xenotime +/- ilmenite is located in a millimetric 17 18 greenschist layer whose temperature is estimated at 600-550°C. Accessories chemistry in this sample 19 allowed in situ dating by LA-ICPMS on thin section in textural context. In the same sample, we 20 performed U-Pb zircon dating, constraining the magmatic age, as well as U-Pb monazite, xenotime 21 and titanite dating for the metamorphic evolution. In a Tera-Wasserburg diagram, monazite, xenotime 22 and titanite yield 161.3 +/- 4.0 Ma, 161.5 +/- 2.4 Ma and 158.4 +/- 2.3 Ma lower intercept ages,

23 respectively, while the zircon from the same sample indicates an age of 161.0 +/- 0.8 Ma. Finally, 24 zircon dated in an albitite vein also yields a 161.8 ± 1.7 Ma age. These similar ages within the 25 analytical uncertainties show that magmatism and metamorphism were concomitant. Thermal 26 modelling predicts that a 150m thick gabbroic massif crystallizes in a few hundred years and cools 27 down in several thousand years. This is consistent with the ages reported in our study showing that 28 the retrograde metamorphism in this massif records fast cooling. The development of this retrograde 29 metamorphism required multiple fluid infiltrations during cooling. In the studied samples, 4 types of 30 titanites could be distinguished based on their chemistries. 3 types variously depleted in REE are interpreted as related to water-driven fluids while another type has up to 10% REE, Y and Nb and 31 32 suggest a possible felsic source. The two potential sources of water promoting this fast cooling are 33 sea water-derived fluids and magmatic fluids exsolved from felsic veins.

34 Introduction

35 The Chenaillet ophiolite, South of Montgenèvre, in the Western Alps is one of the very well-36 preserved portions of the alpine ophiolites, which represent remnants of the Tethys oceanic domain 37 (Figure 1). The alpine Tethys developed as a rather narrow basin, with a maximum width of less than 800 km and a very low spreading rate. It formed during a short-lived phase of magmatism between 38 39 165 Ma and 155 Ma (Manatschal and Muntener, 2009; McCarthy et al., 2021; Tribuzio et al 2016). 40 Alpine ophiolites constitute a heterogeneous lithosphere similar to that formed at slow/ultra-slow spreading ridges or ocean-continent transition. They are mainly composed of variably serpentinised 41 mantle peridotites and irregularly distributed magmatic rocks composed of gabbroic lenses and dis-42 43 continous basaltic cover. Gabbros, troctolite, diorite and albitite are commonly found in alpine ophiolites and are thought to be the result of fractional crystallization of evolving melts and/or the inter-44 45 action between a fractionating crystal mush with an external evolved melt (Rampone and Sanfilippo, 2021). Basaltic dykes are rare and the sheeted dyke complex associated with classical Penrose-type 46 47 model of ophiolites is lacking. Overall, these magmatic rocks have a geochemical affinity of MORB, 48 similar to that of oceanic basalts and kilometre-scale detachment faults accommodated the exhuma-49 tion of mantle rocks and gabbros to the sea floor. Some of these ophiolites are formed in the mantle 50 of the continental margin and represent ocean-continent transition (OCT) while others constitute in-51 tra-oceanic domains (Manatschal and Muntener, 2009).

52 According to these authors, the Chenaillet ophiolite would represent an intra-oceanic domain. The massif of the Mont Chenaillet has overlapped the continental crust and displays only weak effects 53 54 of alpine deformation and metamorphism related to the alpine collision at 33 Ma. This ophiolite is 55 characterized by the occurrence of exhumed serpentinised mantle, intruded by small lenses of gabbros; 56 a voluminous volcanic complex is fed by rare dykes (Mével et al., 1978; Bertrand et al., 1982, 1987; Caby, 1995: Chalot-Prat, 2005: Manatschal et al. 2011 and reference therein). In the Chenaillet massif, 57 58 various rock types such as gabbros, troctolite, diorite and albitite, have been dated (Costa and Caby, 59 2001; Chalot-Prat, 2005; Desmurs et al., 2002, for a review see Li et al., 2013). These latter suggested 60 that the troctolites and albitites crystallized synchronously at about 165 Ma, which is consistent with 61 age estimates of the mantle exhumation of the Alpine Tethys ocean after continental breakup 62 (Manastchal and Muntener, 2009). This date is also consistent with the middle-bathonian age of the 63 oceanic sediments of the neighbouring Lago Nero-Replatte unit which is considered to be the base of the sedimentary succession associated with the ophiolite body (Cordey and Bailly, 2007). 64

While previous geochronological works focused on the emplacement and crystallization of magmatic rocks, the present study aims at distinguishing the magmatic event by analyzing the zircons of an albitite vein (CH4) and of a (meta-)gabbro (CH1) from the cooling event by analyzing the various REE-bearing minerals associated with the metamorphism of this metagabbro. Using U-Pb and trace elements results, we discuss the cooling rate of this gabbro massif by comparing ages obtained with a simple thermal modeling, and conclude by using the chemical signature of titanite on the nature of the fluids which can contribute to this cooling.

72 Geological background

73 On the SW ridge (crest) of Mont Chenaillet, a massif of gabbro forms a lenticular body from 74 (of) 50 to 150 m thick and nearly 2 km long. It is intrusive into the serpentinites and sometimes directly overlain by the pillow lavas (Figure 2). According to Manatschal et al. (2011), the contact 75 76 between the serpentinites/gabbros and the lavas is defined by a detachment fault along which the serpentinites/gabbros were exhumed at the seafloor level before the emplacement of lavas flows. The 77 latter are fed by a few basaltic dikes that crosscut both gabbros and serpentinites: The voluminous 78 79 volcanic complex was built later than the gabbroic complex: basalts and gabbros have been suggested 80 to originate from the same magma source, but the plutonic system do not contribute to the volcanic 81 complex (Bertrand et al., 1987).

82 The lithology of this gabbro massif itself is mostly composed of coarse-grained 83 clinopyroxene-rich gabbros but other lithologies such as troctolites, diorites and albitites, can be 84 found. Troctolites (or more accurately metatroctolites) and olivine gabbros mainly occur at the base 85 of the unit: the continuous transition between gabbros - olivine gabbros and troctolites suggests that 86 these rocks crystallised synchronously. Dolerites also occur as rare dykes or small massifs. Finally, albitites form centimetric to metric dikes within the gabbro massif. One exception is a small 87 88 decametric massif in the serpentinites, at « la Cabane des Douaniers » locality, which has been dated 89 by Li et al. (2013). The entire ophiolitic massif recorded an oceanic seafloor metamorphism prior to a low grade alpine metamorphism (Mevel et al., 1978; Bertrand et al., 1987). 90

91 Lithology and petrography of the gabbroic rocks

Petrography of the gabbros stricto sensu is diversified. The magmatic ophitic textures is locally affected by high temperature ductile shearing (Caby 1995) and the deformation is heterogeneous. Gabbros are coarse- to fine-grained and the variation in crystal size can be sharp 95 (Figure 3). These sharp boundaries could indicate possible replenishments or re-injections of magma
96 at different stages of the gabbro crystallisation/cooling evolution.

97 Here we describe three typical samples of gabbros s.s. and one metatroctolite representative 98 of the massif. The samples CH1 and CH4 were collected from the SW ridge of the Mont Chenaillet, 99 on the centre of the gabbro lens (44°53'53" N ; 6°44'3.35"E); the CH3 sample comes from the 100 northern margin of the gabbro massif, in contact with the serpentinites, next to an oceanic detachment fault (44°54'26.5" N; 6°43'48.55"E; Figure 1). In the following, we only describe the petrography of 101 102 the metatroctolite (CH5) but will not present chemical analyses related to it. This sample is important 103 to understand and discuss the fluid origins affecting the gabbro massif. The mineralogical 104 assemblages are listed in the Supplementary data 1.

105 <u>Sample CH4:</u> The rock is an undeformed gabbro crosscuts by a centimetric thick vein of 106 albitite. The gabbroic part of the sample is coarse-grained with an ophitic texture. Clinopyroxene and 107 plagioclase are the main minerals and are centimetric in size. Clinopyroxene are sometimes rimmed 108 by a thin corona of brown amphibole (<0.1mm).

The albititic vein present in the sample has an irregular and diffuse contact with the gabbro, suggesting that the melt feeding the felsic vein intruded the gabbro when it was not completely solidified. It is mostly made up of albitic plagioclase, apatite, ilmenite, rare epidote and chlorite. Browngreen amphibole crystals representing the only ferromagnesian mineral (Table 1) in this vein, are rare. Some euhedral and cracked zircon crystals of several hundred micrometers in size also occur (cathodoluminescence image in Figure 11b). -Late fractures filled with epidote and actinolite crosscut the rock.

Sample CH3: This sample is collected on the strongly deformed edge of the gabbro at the top
of the lens which is in contact with the serpentinites, just below the oceanic detachment fault (near

118 section I of Manatschal et al., 2011; Figures 2 and 4). The gabbro has been metamorphosed at granu-119 lite/amphibolite conditions as indicated by dark brown amphibole as the main ferromagnesian mineral 120 and minor clinopyroxene. Centimetric porphyroclasts of brown amphibole are wrapped by a well-121 developed foliation (Figure 4). This brown amphibole is deformed and mantled by light brown and 122 green coronitic amphiboles. The light brown amphiboles are associated with ilmenite (Figure 5), 123 while the green amphiboles are associated with titanite (Figure 6)., Rutile exsolution lamellae has been 124 observed within titanite and are related to the replacement of ilmenite. Finally, another generation of titanite occurs in late fractures.Plagioclase is often recrystallised in an aggregate of fine crystals of 125 sodium-rich compositions close to albite (Table 1). When present, clinopyroxene is also surrounded 126 by a corona of dark brown to light brown and green zoned amphiboles, similar to that of the surround-127 128 ing amphiboles. Contrary to the undeformed CH4 sample, the abundance of amphiboles highlights 129 thatthis sample is heavily amphibolitized.

130 Sample CH1: The rock is affected by anastomosed high temperature ductile shear zones 131 marked by the development of a pronounced metamorphic layering, consequently the rock can be 132 defined as metagabbro. The mineralogical association is mainly made up of clinopyroxene, brown to green amphibole and plagioclase rich in albitic end member (Table 1). Accessory minerals are apatite, 133 ilmenite, titanite (Figure 8), cracked zircon crystals (cathodoluminescence image in Figure 12a) and 134 a few monazite (Figure 8c) and xenotime crystals (Figure 8d). It is worth noting that feldspar is black 135 with a dusty appearance: it is replaced by a fine aggregate of epidote, albite-oligoclase, +/-chlorite 136 corresponding to the prehnite - pumpellyite metamorphic facies. The metagabbro exhibits coronitic 137 texture similar to CH3 sample. However more complex textures can also be observed (Figure 7). 138 139 From clinopyroxene to plagioclase, clinopyroxene-brown amphibole symplectites replace the porphyroclasts of magmatic clinopyroxene (CpxMag). This pyroxene is recrystallised into an aggregate 140 141 of neoblastics clinopyroxene with brown hornblende (Cpx2 + bHbl) in a granulite metamorphic fa-142 cies conditions. Then, a single brown amphibole gradually changes to a green hornblende (gHbl) and corresponds to an amphibolite facies stage. The green hornblende is finally progressively replaced by
actinolite with associated chlorite and epidote (Act+Chl+Ep) corresponding to the greenschist facies.

In this sample, a millimeter wide shear zone is identified and contains a string of titanite +/ilmenite, monazite and xenotime grains surrounded by green amphibole and plagioclase (Figure 8). Mineral textures reveal three titanite populations in this rock: (1) titanite associated with the green coronitic amphibole (Figure 6) (2) titanite associated with other accessory minerals in the tiny ductile shear zone (Figure 8) and (3) titanite recrystallised with rutile, after ilmenite (Figure 9).

Sample CH5 : Metatroctolites are abundant on the few tens of meters at the base of the massif.
The ferromagnesian minerals are largely dominant over the plagioclase. Another notable outcrop from
which the sample CH5 (Figure 10) was collected is located on the middle of the SW ridge of the Mont
Chenaillet. In all these rocks, olivine is always absent and is replaced, at the contact with plagioclase
by a coronitic aggregate composed of amphibole (tremolite) enclosed by a chlorite rim. Rare
clinopyroxene, brown and/or green hornblendes and oxides can also be found.

156 Analytical techniques

157

Electron probe microanalysis (EPMA)

Titanite and monazite were analysed for major and minor elements with an EPMA CAMECA SX100 158 at Laboratoire Magmas et Volcans (LMV). For titanite, analyses were made with an accelerating volt-159 age of 20kV and a 40 nA beam current. The crystals used for analysis were PET for Ca, Ce and S, 160 161 TAP for Si, Na and Y, LPET for P, Cl, La and Sr, and PC0 for F and O. For monazite, analyses were 162 made accelerating voltage of 15kV and a 40 nA beam current. The crystals used for analysis were 163 PET for Ca, Si, La, Th, U and Ce, LPET for P, Y and Pb, and LLIF for Pr, Nd, Sm and Gd. Several trace elements in these minerals were also analysed for comparison with laser ablation ICP-MS (LA-164 165 ICPMS) data or when these minerals where too small. The different mineral studied in this contribu-166 tion were imaged for back-scattered electrons (BSE) using this microprobe.

168 Trace element analyses

169 Trace element analysis of titanite was done by laser ablation-inductively coupled plasma mass spectrometry (LA-ICP-MS) using a Thermo Element XR coupled to a 193nm excimer laser 170 (Resonetics Resolution M-50E) at LMV. The spot size was 20 µm with a repetition rate of 1 Hz and 171 172 a fluence of 3 J/cm². We purposely set a low frequency to avoid drilling through titanite too quickly. 173 Each run lasted 20 seconds of background acquisition plus 90s of analyses. Each sequence was bracketed by two analyses of GSE-1G or GSD-1G standards at the beginning and at the end of the sequence 174 (Jochum et al., 2005). Khan titanite reference material (Heaman, 2009) was regularly analysed 175 176 throughout the analytical session to monitor data quality at the same spot size as the analysed un-177 knowns to account for downhole fractionation. Hf content was monitored during analysis of titanite in order to identify potential micro inclusions of zircon. All analyses with Hf content above the back-178 179 ground values were discarded. Internal normalisation for LA-ICP-MS data was done using ⁴³Ca and 180 data processing was conducted using the GLITTER software (Griffin, 2008).

181 *U-Pb dating*

182 Zircon, monazite, titanite and xenotime have been analysed in thin section by LA-ICP-MS (La-183 boratoire Magmas et Volcans, Clermont-Ferrand, France) in order to control the position of the grain 184 relative to the textures observed in the sample. These minerals were ablated under pure He using a 185 Resonetics Resolution M-50 system equipped with a 193 nm Excimer laser coupled to a Thermo Element XR sector field ICP-MS using a jet interface high-capacity pumping device for zircon and 186 titanite or an Agilent 7500 cs quadrupole ICP-MS equipped with a dual pumping system for monazite 187 and xenotime. N₂ was supplemented to Ar and He carrier gas for sensitivity enhancement (Paquette 188 189 et al., 2014). The laser operated with a spot diameter of 27 µm, a repetition rate of 3 Hz, and a fluence

190 of 2.5 J/cm² for zircon and titanite and a spot diameter of 9 μ m, a repetition rate of 1 Hz, and a fluence 191 of 4.0 J/cm² for monazite and xenotime, respectively.

The instruments were tuned to maximise the ²³⁸U intensity and minimise ThO⁺/Th⁺ (<1%) using 192 193 the NIST SRM 612 glass. Background levels were measured on-peak with the laser off for ~30 s. followed by ~60 s of measurement with the laser firing and then ~10 s of washout time (Hurai et al. 194 195 2010). Reduction of raw data was carried out using the GLITTER® software package (van Achterbergh et al. 2001). Isotope ratios were corrected for laser-induced and instrumental mass fractionation 196 via sample-standard bracketing using the GJ-1 zircon reference material (Jackson et al., 2004) for 197 198 zircon and titanite (Fallourd et al., 2014) and the Trebilcock monazite reference material (Tomascak et al., 1996) for monazite and xenotime, respectively. The ²³⁵U signal is calculated from ²³⁸U based 199 on the ratio ${}^{238}U/{}^{235}U = 137.818$ (Hiess et al. 2012). The 91500 zircon reference material (Wiedenbeck 200 et al. 1995) and the Itambe and Bananeira monazites (Goncalves et al., 2016) were analysed along 201 202 with the samples to independently monitor the external precision and accuracy of the measurements. Common Pb was not corrected owing to the large isobaric interference of ²⁰⁴Hg. Concentrations of 203 204 U. Th. and Pb were calculated by normalisation to the certified composition of GJ-1 reference material. ²⁰⁷Pb/²⁰⁶Pb versus ²³⁸U/²⁰⁶Pb diagrams (Tera and Wasserburg 1972) were generated using 205 Isoplot/Ex v. 2.49 software package by Ludwig (2001). Error ellipses for each point are quoted at the 206 207 2σ level.

208 **Results**

209 Mineral chemistry and Geothermometry

The metamorphic minerals are brown to green amphiboles and actinolite, epidote, albite – oligoclase, chlorite, ilmenite, titanite and titanite-rutile (after ilmenite). In the classification for calcium amphiboles by Leake et al (1997), amphiboles ranged as magnesio-hornblendes and actinolites (Table 1). The colour of the amphibole, brown to green, depends on the titanium content 9 214 of the mineral. Primary brown hornblende of sample CH3 is rich in titanium and range in composition 215 between 2.5 and 3 wt% TiO₂. On the other hand, coronitic light brown hornblende TiO₂ content is 216 around 1.50 wt% while below 0.40 wt% for green amphibole. The concentrations of brown and green 217 hornblende located in coronas of CH1 metagabbto are 2.66-1.90 wt% and around 0.40 wt% 218 respectively. In this sample, green actinolite of the tiny shear zone which contains the string of titanite +/-ilmenite, monazite and xenotime has similar low values TiO₂ (≈ 0.40 wt%). Finally, in CH4 219 sample, TiO₂ concentrations in the green hornblendes of the albititic vein are 1.50-1.60 wt%. Brown 220 221 hornblendes, light brown hornblendes, green hornblendes, actinolite are progressively less and less rich in this element. Overall, the composition of plagioclase is very acidic in all rocks: it ranges from 222 albite to oligoclase (Table 1). 223

Provided that a titaniferous buffer mineral as titanite, ilmenite or rutile is present, the change from brown to green amphibole reflects a decrease in the concentration of this element and of the temperature. The concentration of Ti is temperature-dependent and can be used as a robust geothermometer (Otten, 1984; Ernst et Liu, 1998; see below). In a first approach, the brown to green colors of the hornblendes are good qualitative thermometric indicators and reflect respectively high to low temperature conditions of the granulite and amphibolite facies; actinolite is evidence of greenschist facies conditions.

231 Temperature estimates were acquired by applying amphibole-based geothermometers. We used the hornblende-plagioclase geothermometer of Holland and Blundy (1994; edenite-tremolite 232 233 calibration) and the amphibole-only thermobarometers by Ernst and Liu (1998) and Putirka (2016). 234 We previously noted that the mineralogical assemblages in a single rock are not always in equilibrium and record different stages of the thermal history of the massif. Accordingly, the hornblende-235 236 plagioclase geothermometer must be used with caution and the equilibrium between the mineral pairs 237 must be carefully checked. On the other hand, geothermometers only based on the amphibole 238 composition do not have this drawback. The semi-quantitative amphibole thermobarometer of Ernst

239 & Liu (1998) is based on Ti content of the M2 site that increases with temperature. The use of Ti 240 thermometer requires an excess of Ti in the system: we assume that this condition is satisfied because 241 ilmenite and/or titanite are always present. The accuracy of this thermometer has been estimated at the Institut für Mineralogie of Hannover (Germany) using published and unpublished experimental 242 243 data (J. Koepke, pers. Comm.). The equation of this geothermometer is given in France et al. (2021). 244 For the amphibole-only thermobarometer of Putirka (2016), we used equation 6 with a lithostatic 245 pressure of 0.2 Gpa, which is compatible with the depth of gabbro emplacement in-a crust formed at slow spreading ridges (e.g. Canales et al. 2017). In any case, equation 6 of the Putirka thermometer 246 is almost insensitive to small pressure changes (2.4°C/0.1 GPa). It has to be noted that, the amphibole-247 only thermobarometer of Putirka, (2016) was calibrated for igneous systems with T>650°C and 248 249 therefore is preferably suitable for estimating temperature conditions from igneous and high-grade 250 metamorphic rocks (Molina et al., 2021).

251 Temperatures obtained for the two samples CH1 and CH3 with both amphibole-only thermometers for brown amphiboles are consistent and vary between 950°C and 850°C (Table 1). On 252 253 the other hand, the hornblende-plagioclase geothermometer using brown amphibole gives lower results (790-820°C, Table 1). This discrepancy between the amphibole-only and the hornblende-254 plagioclase geothermometers can be explained by the fact that plagioclase of acidic composition is 255 256 no longer in equilibrium with high temperature Ti-rich amphiboles. In general, the temperatures 257 recorded by all geothermometers using green amphiboles are lower (between 800°C and 550°C; Table 258 1). For the entire range of green hornblende compositions, Ti-in amphibole thermobarometer of Ernst and Liu (1998; «revisited» by Koepke) and the hornblende-plagioclase geothermometer give 259 equivalent results. However, the Purtika's amphibole-only thermometer (2016) tends to give higher 260 261 estimates and overestimates the temperatures of amphibolite and greenschist facies conditions Consequently, we did not apply it to the amphiboles of the greenschist facies. 262

263 In the CH3 sample, oikocrysts of Ti-rich amphibole indicate temperatures between 880°C-264 910°C (therm. Purtika) and 950°C (therm. Ernst et Liu, 1998 « revisited ») (brown amphiboles in 265 Figures 5 and 6; Table 1). Their formation occurs at a late-magmatic stage prior to retrograde metamorphism. The light brown coronitic amphibole, located around the brown primary amphibole and 266 267 contemporary to the ductile deformation, indicates temperatures around 800-750°C(therm. Ernst et 268 Liu, 1998 « revisited »), 800-830 (therm. Purtika) and 730-750°C (therm. Holland and Blundy; Fig-269 ure 5 and Table 1). This highlights that deformation immediately followed the emplacement and the crystallisation of the gabbro. The light-brown- to green amphibole coronas record decreasing temper-270 atures from 800°C (Figure 5) down to 550°C (Figure 6). 271

In the remarkable assemblage around the clinopyroxene of the CH1 sample, temperatures range from 870°C to 570 °C (Figure 7). In the amphibolitic layer containing the string of titanite, monazite, ilmenite and xenotime (Figure 8), we note the consistency of the temperatures obtained with hornblende –plagioclase geothermometer (550-600°C) and those acquired with the Ti-amphibole thermobarometer of Ernst and Liu (1998) (550-600°C). These are the temperatures of the amphibolite-greenschist transition around 550-600°C as attested by the actinolite + plagioclase paragenesis.

According to the amphibole geothermometry, the crystallisation temperature of the albitite vein is around 760 and 780°C (therm. Ernst et Liu, 1998 « revisited »), 815°C (therm. Purtika; Table 1).

Trace elements in titanite

In CH1, three types of titanite in different textural context were analysed : (1) titanite cristallising in the green hornblende corona at the expanse of the Ti-rich brown amphibole, (2) titanite crystallising at the expense of ilmenite (Figure 9) and (3) titanite associated with the string of accessory minerals in a tiny ductile shear zone (Figure 8). In Figure 11a, a diagram reporting Y vs. Nb 12 287 reveals that these three types of titanite are chemically different. Types 1 and 2 have lower Nb and Y 288 contents (145<Nb<1982 ppm and 80<Y<18328 ppm, respectively), while type 3 has high Nb and Y 289 contents (2764<Nb<5158 ppm and 19163<Y<29017 ppm, respectively). Type 3 has overall much-290 richer trace elements content than types 1 and 2 (Table 2 and supplementary data 2). In CH3, titanite 291 located within the green amphibole corona (type 1) have the same chemical characteristics as for CH1 292 sample (Table 2 and supplementary 2). In CH3, another type of titanite (type 4) occurs in late frac-293 tures. Although most trace elements in type 4 have fairly similar content to types 1-2 (Table 2 and supplementary data 2), it has generally higher Nb, Cr, V and Sn contents (77-250 ppm, 47-118ppm, 294 353-594 ppm and 35-97 ppm) than type 1 titanite (24-111 ppm, 9-97 ppm, 247-480 ppm and 15-35 295 296 ppm respectively).

297 Chondrite-normalised REE patterns (Figure 11b) also distinguish the different types of titan-298 ites described above: type 1 titanites from CH3 sample have low REE content, rather flat patterns and 299 moderate positive to negative Eu anomalies. In contrast, type 3 from CH1 sample corresponding to 300 titanite from the accessory mineral of the ductile shear (Figure 8), define a tight group 20-200 times 301 richer in REE content, with quite flat REE patterns and a strong negative Eu anomaly (Figure 11b, 302 Table 2 and supplementary data 2). Notably, type 3 titanite define a tight group of analyses in a 303 Chondrite-normalized diagram while the other titanite types analyses are more scattered. Finally type 4 titanites from sample CH3 display similar REE patterns to those of type 1 from the same sample 304 305 but with a marked positive Eu anomaly. Type 4 titanite texturally occurs in late fractures and Eu 306 anomaly in this titanite type is most probably inherited from late fluid circulation and local feldspar alteration. 307

Ages of the magmatism recorded by zircon

310 The zircons from the CH1 gabbro and the CH4 albitite vein allow dating the crystallisation 311 and the emplacement of the massif. The zircon crystals of the gabbro CH1 are 30-100 µm long, 312 subhedral and sometimes cracked. Cathodoluminescence images (Figure 12a) show oscillatory 313 zoning: such internal structure is well consistent with those of zircons crystallised from mafic magmas 314 (Corfu et al 2003, Paquette et al., 2017). In the metagabbro, U and Th contents are very variable, from 315 9 to 342 ppm and from 2 to 130 ppm, respectively, whereas the Th/U ratios also yield magmatic values, ranging from 0.10 to 0.49. Reported in a Tera-Wasserburg diagram, thirty-four of the thirty-316 five analysed points plot on a discordia line which allows to calculate a lower intercept age of 161.0 317 +/- 0.8 Ma (Fig.12a). 318

319 In the albitite vein (CH4), several crystals form rectangular half-millimetre tablets with square 320 or diamond-shaped cross-sections. Slight localised alteration along fractures is noticeable in 321 cathodoluminescence (Figure 12b). However, the network of these fractures is sufficiently spaced to 322 allow analyses by laser-ICPMS. The U and Th contents of zircons from CH4 are very low, from 8 to 31 ppm and from 2.8 to 19.5 ppm, respectively, in agreement with a mantle-derived source. The Th/U 323 324 ratios ranging from 0.36 to 0.65 display typically magmatic values (Table 3). Reported in a Tera-Wasserburg diagrams, the seventeen analytical points define a discordia line which yields a lower 325 326 intercept at 161.8 +/- 1.7 Ma (Figure 12b).

Both dates, 161.8 +/- 1.7 Ma and 161.0 +/- 0.8 Ma, attest of the age of the emplacement of
the gabbroic massif and associated rocks.

329 Ages of the cooling recorded by the metamorphic chronometer minerals: monazite, xenotime
330 and titanite

All three metamorphic chronometer minerals, monazite, titanite and xenotime are found in a
 tiny shear zone in sample CH1. They date this shearing event which occurs during the cooling of the
 gabbro when this one reached the greenschist facies conditions. A cluster of a few rounded grains
 14

| 334 | (around ten) of monazites ranging in size from 5 to 20 microns is associated with the string of titanite |
|-----|--|
| 335 | and ilmenite. (Figure 8c). Composition of monazite is relatively homogeneous. UO2 contents are low |
| 336 | and vary between 0.15 and 0.42 %, while ThO2 varies from 1.36 to 5.06 % (Table 3). |

Four small grains of xenotime are included in the string. Only a single grain of 50x30 microns
size could be analysed for dating. (Figure 8d).

We noted previously that three populations of titanite can be distinguished by their petrographic textures and their compositions in the sample CH1 (Table 2 and supplementary data_2). Crystals associated with green Hbl + Pl coronas around Cpx/brown hornblende and rare crystals scattered in the rock are poor in trace elements (Figure 6). Those included in the string of titanite +/ilmenite associated to monazite and xenotime grains and located in a millimetric amphibolitic layer (Figure 8) are rich in trace elements (Table 2 and Figure 11). Their fairly high Th and U contents (up to 222 ppm and 187 ppm respectively) allow dating of these minerals.

The analytical points of the U-Pb dating of the three minerals: monazite, xenotime and titanite plot along discordia lines and yield lower intercept ages at 161.3 +/-4.0 Ma, 161.5 +/-2.4 Ma and 158.4+/-2.3 Ma, respectively (Figure 13). These three ages are consistent within the analytical uncertainties.

350 Discussion: Retrograde evolution of the (meta)gabbro of Mont Chenaillet 351 Dating and modeling the cooling

352 Metamorphism and cooling of the gabbro

In the Mont Chenaillet massif, isotropic gabbros, foliated metagabbros and amphibolites coexist, showing that deformation and metamorphism are unevenly distributed. The petrographic relationships in the studied rocks show a chronology in the crystallisation of the amphiboles, gradually passing from brown to green, then to actinolite, this evolution being documented in the 15 357 Figure 7. The mineral assemblages are consistent with peritectic reaction as clinopyroxene + melt + 358 fluid \rightarrow amphibole + plagioclase and the hydrothermal metamorphic reactions: clinopyroxene + 359 calcic plagioclase + fluid \rightarrow amphibole (+ clinopyroxene 2) + sodic plagioclase and dark brownamph + An-rich Pl1 = light brown amph /green amph + Ab rich Pl2 + ilmenite/titanite. In 360 361 metatroctolite outcrops, the absence of olivine supposes the involvement of the reaction olivine + 362 plagioclase + fluid = tremolite + chlorite (Figure 10). These amphibole-forming reactions were continuously retrogressive and they testify that the different rocks record the cooling history of the 363 massif. These minerals are, however, unevenly distributed throughout the whole massif. This requires 364 a pervasive and continuous infiltration of aqueous fluids/hydrated melt over time but which are more 365 366 or less channelised.

367 In this contribution, we aimed at dating different minerals testifying of the magmatic (zircon) 368 and cooling history (monazite, titanite, xenotime). The dates recorded in the zircon, 161.8 +/- 1.7 Ma 369 and 161.0 +/- 0.8 Ma, constrain the age of the emplacement of the gabbroic massif and associated rocks. They are similar within uncertainties with those published in Li et al. (2013). They are con-370 371 sistent with the ages of the oceanic sediments of the Lago Nero-Replatte unit, the neighbouring ophiolite body which contains radiolarites providing a middle bathonian age between 166 and 162 Ma. 372 (Cordey and Bailly, 2007). On the other hand, the three metamorphic minerals, monazite, titanite and 373 xenotime (belonging to the greenschist paragenesis of the tiny shear zone of sample CH1) crystallised 374 375 between 550 and 600°C and thus date the transition from amphibolite facies to greenschist facies 376 during the cooling of the gabbro. The three ages obtained: 161.3 +/-4.0 Ma, 161.5 +/-2.4 Ma and 158.4+/-2.3 Ma, respectively (Figure 13) are consistent within the analytical uncertainties. Unfortu-377 nately, the ages achieved by the different mineral chronometers: zircon for the magmatic episode, 378 379 monazite, titanite and xenotime for the metamorphic one, between 161 and 158 Ma, are similar within the analytical uncertainties and do not allow to specify the chronology of this cooling from magmatic 380 381 temperatures to those of the greenschist facies (550 - 600°C). This attests that the magmatism and the metamorphism associated with the cooling of the magmatic rock follow one another in a very shorttime.

The metagabbros also present very low temperature mineral assemblages (Prehnitepumpellyite facies), such as the fine alteration of plagioclase in epidote and albite (Figure 7), and maybe the alteration of ilmenite into titanite + rutile (Figure 9), or else some minerals in tension cracks. We agree with Mevel et al. (1978) and Bertrand et al. (1987) that this very low temperature event is difficult to date. It is still unclear whether they record the end of the cooling of the gabbro, contemporaneously with the serpentinisation of the surrounding peridotites or if they are linked to the obduction of the ophiolite and the alpine collision.

391 Modelling the crystallisation and cooling of the (meta)gabbro of Mont Chenaillet

392 In order to assess the duration of the cooling process, we have established simple conductive thermo-kinetic models to reproduce the thermal evolution obtained with the petrologic study. The aim 393 394 is to estimate the thermal evolution and the lifespan of the crystallisation and cooling of a 150 m thick 395 gabbroic lens. The key question is: Which duration is required to solidify it? We used a transcription 396 for PC of the CONTACT program (Peacock, 1989; Spear, 1989; Spear & Peacock, 1990; Spear et al., 1991) that simulates contact metamorphism by using an explicit finite difference algorithm to solve 397 398 the one-dimensional heat transfer from an intrusion to the intruded host rock. The model supposes 399 some simplifications: the igneous body is instantaneously intruded and we do not take into account 400 advective heat transfers during the ascent of magma from the underlying reservoir. Heat transfers 401 only proceeds by conduction while hydrothermal circulation in the gabbro (attested by the abundance 402 of hydrated minerals) enables a fast heat transfer (e.g. Zhang et al., 2014). The model assumes a single 403 injection without replenishment of the magmatic lens. In the studied case, this condition seems to be 404 more or less satisfied, as evidenced by the scarcity of intrusive contacts of gabbro in gabbro (Figure 405 3), or between the different lithologies : troctolite – gabbro – plagiogranites (diorite and albitites), 406 thus suggesting a limited replenishment or reinjection of the magmatic lens.

407 Thermodynamic constants have been selected following Spear & Peacock (1990), Cannat et 408 al. (2004), Lesher & Spera (2015) and Gillis & Coogan (2019) with a thermal conductivity of 3.0 W/m/K, a rock density of 3000 kg/m³, a specific capacity of 1200 J.kg/K and a latent heat of 409 crvstallisation of 400 kJ/kg. We set the liquidus at 1200°C, a realistic temperature for a relatively 410 411 primitive basaltic melt, and an almost dry solidus around 1050°C. According to Escartin et al (2003) 412 and Manatschal et al. (2011) the gabbros are intrusive in very shallow levels in a cold lithosphere at 413 the brittle-ductile transition. If the gabbro is exhumed along an oceanic detachment fault, the 414 temperature of the surrounding rocks has changed progressively during the exhumation since the emplacement in a high temperature environment to the seafloor. This variation of temperature during 415 the exhumation and the rate of this exhumation will determine the cooling rate of the gabbro. 416 417 Consequently, we chose an average fixed temperature of 550°C for the surrounding rocks which 418 corresponds to the estimated temperature of the tiny ductile shear zone containing the three 419 chronometer minerals: titanite, monazite, and xenotime (Figure 8)

420 Our straightforward thermal modelling predicts that the magmatic lens is completely 421 solidified in about 350 years and cooled to 550-600°C in less than 8000 years (Figure 14). If the 422 cooling started in a warmer environment, in the range of 750-700°C, and then gradually decreased, 423 this would only change our result by a factor of 3 or 4. However, as already highlighted, the cooling 424 of the Mont Chenaillet gabbro takes place in a context of strong hydrothermal convection and 425 therefore these estimates using such conductive thermal models can only be maximum. These surely 426 greatly overestimate the time of cooling. Nevertheless and despite the uncertainties of this calculation, these models give an order of magnitude of the cooling time of a gabbro massif like that of Mont 427 428 Chenaillet. They are in agreement with the proposals of Escartin et al. (2003) who suggest that the 429 distribution and duration of gabbro emplacement had to be limited in space and time. Although the 430 cooling rates estimated by Coogan et al (2007) or Faak and Gillis (2016) are lower than our results, 431 these authors demonstrate that the cooling of gabbros in the oceanic crust is very fast. On the contrary,

the cooling rates considered by Zhang et al (2013) are significantly higher in the context of a vigorous hydrothermal circulation. In a similar way, Mc Caig et al (2010) suggest that hydrothermal discharge along detachment fault favours rapid cooling of the gabbros). In all cases, our estimations are far below the analytical uncertainties of our geochronometers and nicely explain why we cannot resolve the different stages of the cooling history ages with this method.

437

Two origins for the sources of water

438 The multiple generations of hydrated minerals crystallising throughout the retrograde thermal evolution from the late-magmatic stage (sample CH3: 950°C) are evidences of a permanent, albeit 439 440 irregularly distributed, volatile bearing agent - rock interaction during multiple fluid infiltration 441 events: brown and green amphiboles and the pervasive low temperature alteration of plagioclase to albite + epidote. Another example of water-rock interaction in the Chenaillet massif is the complete 442 443 transformation of the troctolite olivines to chlorite and tremolite (Figure 10). Coogan et al. (2001), Persev et al. (2015) and Harigane et al. (2019) well summarised the various sources of water that can 444 lead to the hydration of the oceanic crust: (a) a residual hydrous silicate melt derived from the 445 446 fractionation of basalt, (b) an exsolved magmatic fluids from such a hydrous silicate melt, (c) 447 seawater-derived fluids and finally mixtures of these end-members.

In the gabbroic massif of Mont Chenaillet, the scarcity of the differentiated facies (ferro-gab-448 bros, diorites and plagiogranites) precludes the assumption that water of magmatic origin was the sole 449 450 cause of the significant hydration of the gabbro lens. On the other hand, the high amount of amphibole 451 in the CH3 sample close to the detachment fault, which represents a preferential channel for the circulation of the seawater, strongly suggests the major role of seawater-derived fluid in the metamor-452 453 phism of the massif. The extensive alteration of the olivines in the metatroctolites suggests a widespread hydration of these rocks (Figure 10). However, the detailed study of the chemistry of titanite 454 and the fact that their textural context is linked with very different chemical compositions (Figure 11) 455

456 suggest an infiltration of fluids of various nature and hydrous melts. More specifically, type 3 titanite 457 found within a ductile shear in sample CH1 (Figure 8) have high contents in trace elements (e.g. REE, 458 Nb, Ta, Table 2). Their compositions are characteristics of a felsic melt (Protwake and Klemme, 2005; 459 Hoskin et al., 2000; Bruand et al., 2014). These signatures of the titanite of the ductile shear are very 460 different from the other titanites both found in CH1 and CH3. Indeed, type 1, 2 and 4 have much 461 lower content in trace elements and REE in particular (Table 2 and Fig11). Titanite 1 and 2 chemical signatures are inherited from the reaction of previous Ti-bearing phases (Ti-rich Amphibole for type 462 463 1 and ilmenite for type 2) and are directly linked to changing metamorphic conditions from granulite toward the amphibolite/greenschist facies. Type 4 was only found in late fractures affecting Ch3 464 samples and its chemistry (low REE content and positive anomaly) is most likely linked to the late 465 466 circulation of fluid alterating feldspar. Some authors (eg. Persev et al., 2015) have suggested that local 467 enrichment in trace elements of the gabbros (REE, Y, Nb, ...) could originate from exsolved magmatic fluids released by hydrous felsic melts such as plagiogranites during their crystallisation. Tribuzio et 468 469 al, (2019) recently proposed that the small gabbro massif of Rocher de l'Aigle (north of Mont Chenaillet) would be metasomatised by felsic hydrous melt feeding the dykes of albitite. It has to be noted 470 471 that no intrusive veins at the outcrop scale could be found associated to the micro shear zone in sample 472 CH1ITherefore, instead, the trace element abundance of the type 3 REE-rich titanite (Figure.11b) in this micro shear zone could originate from a metasomatic fluid resulting from the crystallisation of a 473 SiO₂-rich hydrous melt feeding the veins of albitite and percolated into the already partially cooled 474 475 gabbro. The varied composition of the other titanite types suggests a diversity of fluid sources. As we 476 are in a context of vigorous hydrothermal circulation in an oceanic crust, a seawater-derived hydro-477 thermal fluid origin of the principal source of water responsible for the overall hydration of the massif 478 is a reasonable hypothesis during the exhumation of the gabbro along the detachment shear zone. Tribuzio et al. (2019) do not preclude such an origin as they write: "we cannot exclude, however, that 479 480 some of the amphibole (and clinopyroxene) chemical variability reflects replacement and/or over-481 growth by a secondary amphibole in response to interaction of the gabbros with fluids, which could

482 be exsolved from the melt trapped within the deformed gabbros, and/or derived from seawater during483 subsequent exhumation of the gabbros to the seafloor."

484 **Conclusions**

Multiple generations of metamorphic minerals and specially amphiboles are evidence that the 485 gabbro petrographically records different steps of its cooling during exhumation to the seafloor along 486 487 an oceanic detachment fault, suggesting that the rock underwent separate episodes of fluid/rock 488 interaction and/or deformation. The timing of this cooling could be theoretically measured using in situ dating on thin section in textural context of the chronometer minerals linked to this 489 490 metamorphism by LA-ICPMS. The crystallisation age of the gabbro is determined by U-Pb zircon 491 dating at 161.0 +/- 0.8 Ma similar to this obtained in the albitic vein at 161.8 +/- 1.7 Ma, whereas the 492 metamorphic minerals, monazite (161.3 +/- 4.0 Ma), titanite (158.4 +/-2.3 Ma) and xenotime (161.5 493 +/- 2.4 Ma) in a tiny ductile shear zone date a shearing event during the cooling of the gabbro at the transition of the amphibolite and greenschist facies. Unfortunately, the different minerals display 494 495 similar ages within the analytical uncertainties and the cooling age cannot be distinguished from the 496 magmatic age of the massif. Indeed, a simple numerical model confirms that the crystallisation and 497 cooling of the Mont Chenaillet gabbro are extremely fast: the crystallisation happens in a few hundred years and the cooling is completed in a few thousand years. In this way, we show strong evidence for 498 499 rapid exhumation and cooling of the gabbro related to detachment faults in the Chenaillet ophiolite 500 generated in a slowly spreading accretionary system. Even if the cooling age cannot be resolved with 501 the geochronology, the petrological work and the various chemical compositions recorded in titanite. 502 nicely highlighted that the development of this retrograde metamorphism required multiple fluid (and 503 possibly hydrous SiO2-rich melts) infiltration events enhanced by multiple ductile/brittle deformation events during the exhumation. We propose two origins for the source of water : pervasive seawater-504 505 derived fluids and more locally, exsolved magmatic fluids from evolved hydrous silicate melts (plagiogranite veins) and infiltrated into the already partially cooled gabbro. Even if we have no 506 21

evidence, we cannot exclude that the gabbro could be locally metasomatised by felsic hydrous melt
feeding the dykes of albitite as suggested by Tribuzio et al. (2019) in the neighbouring massif.

713 Legends of the figures and tables

Figure 1: Geological map of the Chenaillet Ophiolite; simplified after Manatschal et al. (2011). Red
spot: samples CH1 and CH4; red star: sample CH3.

716 Figure 2: Gabbroic lens (Gb) of Mont Chenaillet . It is intrusive in serpentinites (serp), themselves

717 covered by pillow basalts (Bc) on the western flank of the NW ridge of the Mont Chenaillet. Sample

718 CH3 comes from the top of this lens. View from les Prés du Gondran.

Figure 3: Contact between an ophitic-textured gabbro and a microgabbro. The contact is sharp and
could represent intrusive contact, indicative of a (possible) local replenishment of the magmatic lens.

Figure 4: Metagabbro (CH3), a few meters from the gabbro-serpentinite contact (on the top of the gabbro outcrop of the figure 2). Grey pyroxenes and black amphiboles, both magmatic, are wrapped in a foliation, which is underlined by a black amphibole. Abbreviations in text and figures are from Whitney & Evans (2010).

725

Figure 5: Coronitic amphibole in the metagabbro CH3: the porphyclast of brown amphibole is wrapped by foliation and surrounded by green-brown amphibole and ilmenite, testifying to a ductile high temperature deformation and metamorphism during cooling of the gabbro. microphotography in Plane Polarized Light; white bar: 1mm.

Figure 6: Coronitic assemblage in the metagabbro CH3: microphotography of a pressure shadow of green amphibole (gHbl) – plagioclase – titanite (Ttn) +/-ilmenite (ilm, itself replaced by titanite + rutile as in fig. 9) around a brown amphibole (bHbl) (Microphotography in PPL); white bar: 0,25mm.

Figure 7: Complex coronitic assemblage in the metagabbro CH1: From left to the right, i.e. from the 733 magmatic clinopyroxene clasts to plagioclase: the magmatic clinopyroxene clasts (CpxMag) are re-734 735 crystallized into a fine granoblastic aggregate of Cpx2 wrapped with interstitial brown hornblende 736 (Hbb) (=granulite facies). Then, a single brown amphibole gradually changes to a green hornblende (GHbl) (= amphibolite facies), then to an actinolite associated with chlorite and epidote. 737 738 (Act+Chl+Ep) (= greenschists facies). The plagioclase ("Pl") is black with a dusty aspect: it is replaced by a fine aggregate of epidote and albite (= prehnite - pumpellyite facies). Temperatures in °C 739 according to the Ti-amphibole thermometer of Ernst and Liu (1998, « revisited »). This portion of 740 741 rock records on only 3mm, the cooling of the gabbro through the Granulite, Amphibolite and 742 Greenschists facies. (Microphotography in PPL); white bar: 1 mm.

Figure 8: A string of chronometer minerals in sample CH1: a string of titanite +/- ilmenite grains is located in an amphibolitic layer with a granoblastic texture. a) and b) microphotographs in PPL. In white in c) and d) respectively xenotime and monazite in the string; titanite is dark gray, ilmenite is light gray. Backscattered electron (BSE) images; white bar: 0.4mm in a); 0.2 mm in b).

Figure 9: Destabilization of ilmenite into titanite + rutile needles. Backscattered electron (BSE) image.); sample CH1; white bar: 20µm.

- 749 Figure 10 Photography of a metatroctolite: at the contact with plagioclase, olivine is replaced by a
- romage composed of an amphibole (tremolite) enclosed by a chlorite rim according to
- 751 the reaction Ol + Pl + V = chlorite + tremolite. White bar: 1 cm
- Figure 11 : (a) : Y vs Nb in ppm, (b) Chondrite-normalized REE patterns of the titanites of the meta-gabbros CH1 and CH3. Chondrite values from Boynton (1984).
- Figure 12 Geochronological results: Tera–Wasserburg diagram showing the zircon data of (a) the
- gabbro CH1 and (b) the albitite vein CH4. Cathodoluminescence images of zircons. In a), note the
- oscillatory zoning; in b), a slight alteration is localised at the fractures; the size of the analysis spot
- 757 (30 μ m) is smaller than the size of the fracture network.
- Figure 13 Geochronological results: Tera–Wasserburg diagram showing the monazite, xenotime
 and titanite data of the string of titanite +/- ilmenite of CH1 sample.
- Figure 14 Thermal modelling: modeled evolution of temperature with time at various points inside a 150m thick gabbroic lens. From top to bottom, the temperature - time profiles represent respectively the thermal evolution at the center of the intrusion (75 m) and at various distances from the contact, inside the intrusion. In blue: enlargement for the first 750 years,

764

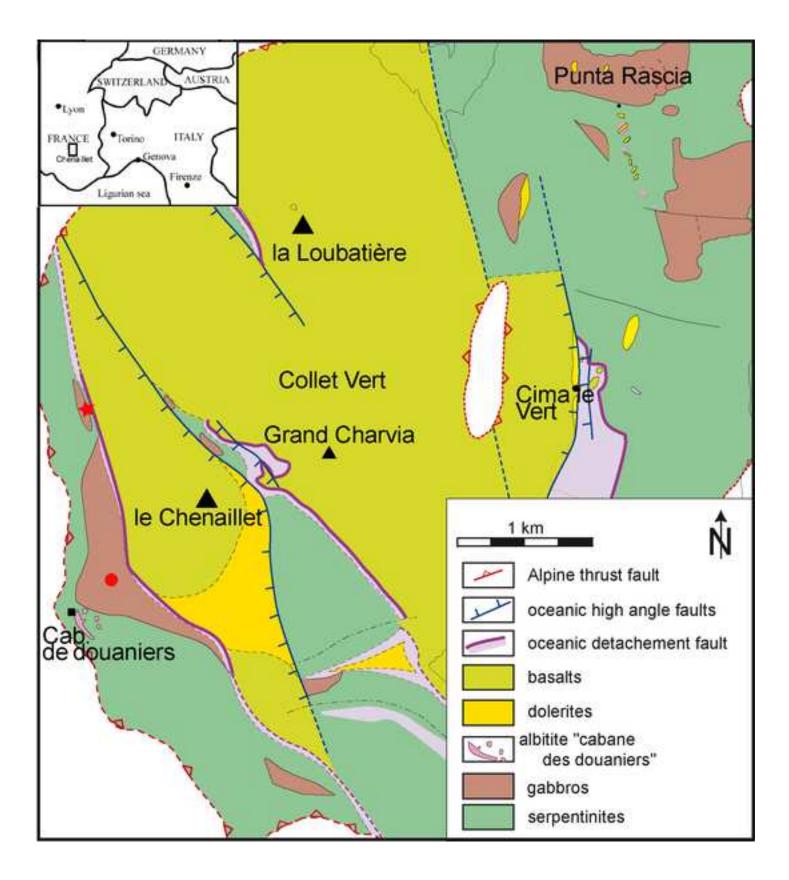

Table 1: Electron microprobe analyses of the major elements of amphibole – plagioclase and geothermometry; H-B : Holland and Blundy (1994), edenite-tremolite calibration. Act-String, Pl-String : actinolite and plagioclase of the string of titanite +/- ilmenite; Cpx: clinopyroxene; BHbl, LbHbl, GHbl:
brown, light brown, green hornblende; Cor : coronitic mineral. Preferred temperature estimates are
in bold. na: Purtika thermometer not applied on greenschist facies amphiboles.

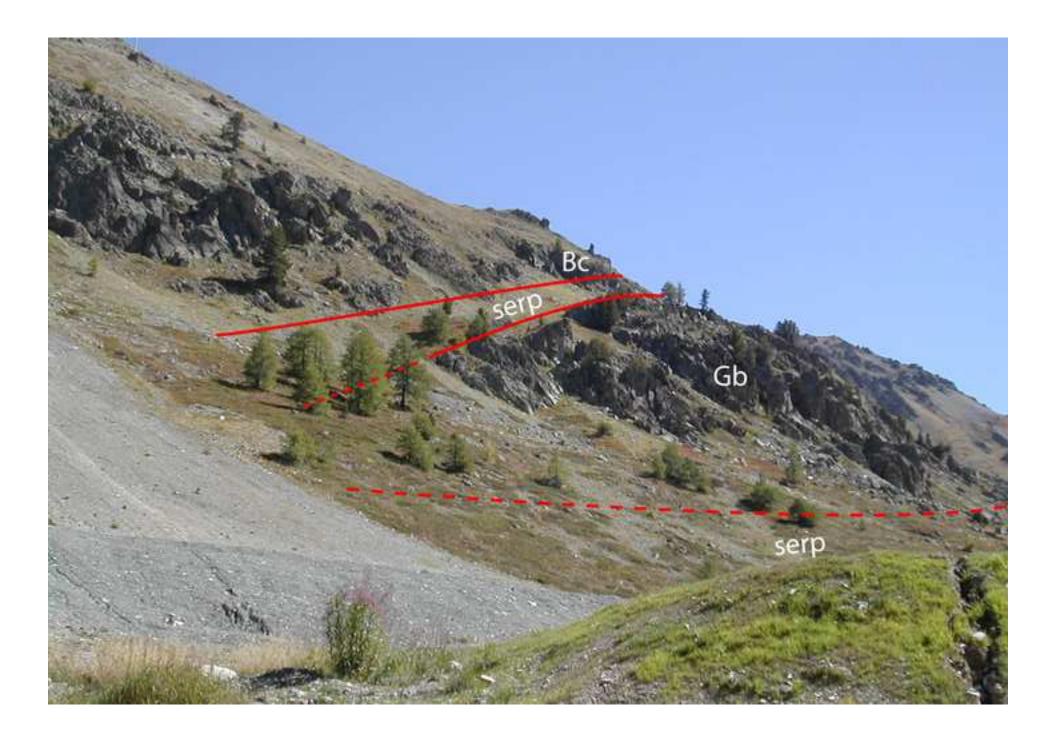

Table 2: Representative analyses of titanite: major and trace elements: Electron microprobe and LAICP-MS analyses.

Table 3:U-Th-Pb dataset for the dated minerals: zircon, titanite, monazite and xenotime obtained byin situ Laser Ablation ICP-MS.

Supplementary data 1: Mineral assemblages and main petrographic features of the studied rocks.
Cpx: clinopyroxene; Clast : porphyroclast; granoblastic: aggregate of Cpx2; Cor: coronitic; Pl:
plagioclase, bHbl, Lb/gHbl: Brown, light brown/green hornblende; Act: actinolite; Chl: chlorite;
accessory minerals: titanite, ilmenite, apatite, zircon, monazite in CH1String; String: string of titanite
+/- ilmenite, monazite, xenotime in a tiny shear zone. +: abundant; -: rare.

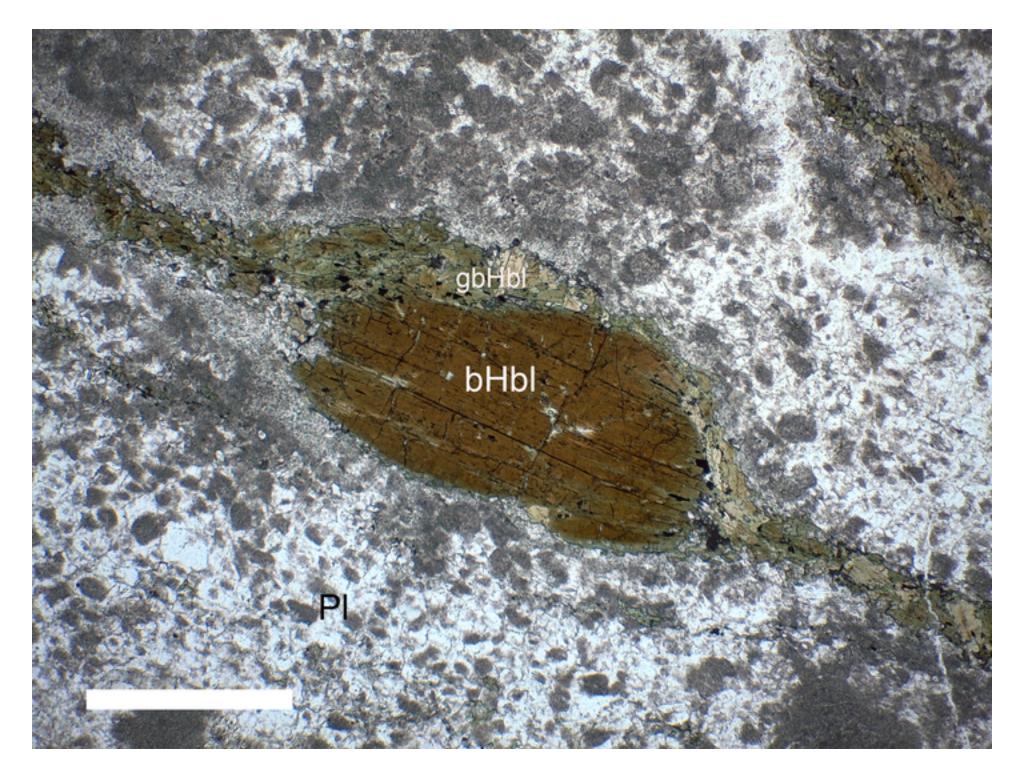

- 779 Supplementary data 2: Analyses of titanite: major and trace elements: Electron microprobe and LA-
- 780 ICP-MS analyses.
