RH: LEMIERRE ET AL.—OLIGOCENE *PELOPHYLAX* FROM France

ABSTRACT—Ranids represent an important part of the extant anuran diversity of Europe. One of the best-known genera is *Pelophylax* (green-water frog). This genus is considered to have arrived in Europe during the Eocene/Oligocene transition, with numerous occurrences of the genus throughout European Oligocene sites. Unfortunately, most of the specimens are isolated bones, hampering our understanding of the diversity and evolution of the genus during this time. We here present the description of an incomplete but articulated anuran skeleton from the earliest Oligocene of Chartres-de-Bretagne (Western France). This specimen, missing its head, preserves almost all postcranial bones articulated and skin impressions. The osteological description allows to assign this specimen to *Pelophylax* kl. *esculentus*, making it one of the oldest known occurrences of the genus. We also suggest that specimens assigned to the late Oligocene “*Rana*” *aquensis* should be referred to the genus *Pelophylax*. The presence of a *Pelophylax* in Western Europe during the early Oligocene indicates that the genus had already spread throughout Europe, no later than 5 Ma after its emergence in the eastern part of the continent. It suggests that *Pelophylax* benefitted from the extinction of ranoids during the “Grande Coupure.”

INTRODUCTION

Anurans have been recovered from numerous Cenozoic sites in Europe, documenting a rich and diverse history of the clade during this period. In peculiar, the Quercy Phosphorites (mostly Eocene/Oligocene deposits; Péliissié et al., 2021) have yielded hundreds of anurans bones, representing most extant anuran clades present in Europe (Rage, 2016). The Phosphorites also document the turnover within neobatrachians anurans during the “Grande Coupure,” with the establishment of “true” ranid taxa during the Oligocene (Rage, 2016; Vasilyan, 2018). Among them, the genus *Pelophylax* (green-water frogs) is thought to have appeared and diversified during the early-middle Oligocene (Chan & Brown, 2017). Unfortunately, the genus is represented only by isolated bones from a single site during the early Oligocene (Sanchíz et al., 1993). Two taxa from the late Oligocene/Early Miocene, “*Rana*” *aquensis* Coquand, 1845 (southern France) and “*Rana*” *meriani* Meyer, 1852 (southern Germany), known by several complete specimens, have been informally assigned to the genus, but several uncertainties remain regarding their attribution (Sanchíz, 1998). Thus, the evolution of the geographical range of *Pelophylax* is almost unknown during a crucial phase of its spread across Western Europe, as the genus is present in most of Western Europe during the Miocene (Roček, 2013). Discovery and identification of specimens of *Pelophylax* from this region would help our understanding of the dispersal and evolutionary history of the genus during the Oligocene.

Our study is focused on the description and identification of a specimen from this geographical area (Fig. 1A, B). The specimen was discovered on July 7, 1922, by the geologist Yves Milon in the Grands-Fours quarry near the city of Rennes (Brittany, western France, Fig. 1C, D). Two days later, the specimen was presented at a session of the Société Géologique et Minéralogique de Bretagne (Dangeard & Milon, 1922). Unfortunately, Milon never described the specimen, and it was considered lost for several decades. One of us (D. Gendry) recently

rediscovered this specimen, along with Milon's identification (an anuran) in the collection of the geological museum of the University of Rennes 1. We took this opportunity to describe the osteology of the fossil and propose a taxonomic attribution. We also discuss its implication for the Oligocene occurrence of ranid taxa in Europe.

GEOLOGICAL CONTEXT

Chartres-de-Bretagne is an ancient complex of quarries located 5 km south of the city of Rennes, within the Cenozoic Basin of Rennes (Fig. 1A). The quarry produced limestone, with numerous open pits present (Vasseur, 1881; Trautmann et al., 2000; Lebrun et al., 2017). The sites are unfortunately backfilled today, and no further investigations are possible. The Oligocene beds of Chartres-de-Bretagne are thick (380 m thick) and have been well-known since the end of the nineteenth century (Vasseur, 1881; Lebesconte, 1879; Allix, 1922; Dangeard & Milon, 1926; Lebrun et al., 2017). The Lower Sapropels Formation is the most basal formation. It forms the majority of the Oligocene deposits (around 280 m) and represents a major regression during the early Rupelian. This bed is overlain by the *Natica crassatina* marls and "Archiacina" limestone formations (52 m thick). These two formations were deposited during a transgressive event that lasted throughout the early Rupelian (Fig. 1B). The uppermost Oligocene formation within the region is the Upper Sapropels Formation (Rupelian; around 6.5 m thick). Within this formation, the foraminiferans *Arenagula kerfornei* and *Archiacina armorica* (*Peneroplis armorica* in Bauer et al., 2016) have been recovered (Bauer et al., 2016; Lebrun et al., 2017). In a previous study (Bauer et al., 2016), the foraminiferan *Archiacina globula* was also mentioned. However, it is a subjective junior synonym of *Arenagula kerfornei* (World Register of Marine Species: <https://www.marinespecies.org>). Both *Arenagula kerfornei* and *Archiacina armorica* are early Rupelian markers for the SBZ 21 biozone (Cahuzac & Poignant, 1997; Bauer et al., 2016). Notably, they are not present in the

1
2
3 101 following SBZ 22 biozone (*Arenagula* is only present in the SBZ 22A of the Aquitaine Basin;
4
5 102 Cahuzac & Poignant, 1997), to which a recent study (Bauer et al., 2016) attributed the Upper
6
7 103 Spropels Formation (at least part of it). Thus, we do not agree with this attribution, and
8
9 104 consider the entire Upper Spropels Formation early Rupelian in age (SBZ 21 biozone; MP21-
10
11 105 22; Speijer et al., 2020).

12
13
14 106 Within the formation, its lower part is composed of greenish interbedded claystones,
15
16 107 marlstones, and limestones. The flora is rich and made up of hydrophilous taxa while the fauna
17
18 108 is composed of lacustrine taxa (fishes and mollusks; Depape, 1926; Gaudant, 1989; Kerforne,
19
20 109 1915; Milon & Dangeard, 1920; Milon, 1930, 1935, 1936; Bauer et al., 2016; Lebrun et al.,
21
22 110 2017). A small fragment of a crocodilian osteoderm was also collected. All these
23
24 111 sedimentological and paleontological elements are consistent with a restricted and quiet
25
26 112 lacustrine environment. The blackish color of the Upper Spropels Formation is also an
27
28 113 indication that the depositional environments was rich in humic materials, and the lake bottom
29
30 114 was likely anoxic (Milon, 1930, 1935; Fig. 1C). Roots, rhizomes, and leaves are exceptionally
31
32 115 well-preserved (Lebrun et al., 2017: pl. B, C). In addition, all known vertebrate specimens
33
34 116 (except the osteoderm) are preserved as articulated skeletons with soft tissues (skin
35
36 117 impressions) preserved (Lebrun et al., 2017: pl. B, C). Therefore, these laminated deposits
37
38 118 likely represent a Konservat-Lagerstätte owing to the exquisite preservation of the fossils. The
39
40 119 single anuran specimen was discovered within the Grand-Fours quarry (La Chaussairie) from
41
42 120 the Upper Spropels Formation (around 30 cm below the top of the bed).

51 122 MATERIALS AND METHODS

52
53 123
54
55
56 124 **Institutional Abbreviations**—IGR, Institut de Géologie de Rennes; MNHN, Muséum
57
58 125 National d’Histoire Naturelle (Paris, France). The specimen is stored within the collection of
59
60

the geological museum of the University of Rennes under the following number: IGR 144547.

Both main slab (M1) and counterpart slab (M2) are catalogued under the same number.

Reflectance Transformation Imaging (RTI)—Most bones are crushed or preserved as partial imprint and thus difficult to identify. RTI is a method that computes an “interactive specimen” in which illumination can be oriented at will (Hammer et al., 2002). This method was used with a custom-made portable light dome (same as used in Cui et al., 2022). Sets of 54 photographs under different LED sources were compiled using the RTIBuilder software. The results RTI files (see supplemental data: 10.5281/zenodo.7223828) can be opened using the RTIViewer software. Both RTIBuilder and RTIViewer are freely available at www.culturalheritageimaging.org. This study is one of the few using RTI to study fossil vertebrate specimens.

Anatomical Comparison—Comparisons were made with the neotype of “*Rana*” *aquensis* (Piveteau, 1927), MNHN.F.AIX355 (“*Rana*” *aquensis*). Comparisons were also made with an unnumbered specimen of *Pelophylax* kl. *esculentus* from the MNHN.

Anatomical Nomenclature—The anatomical nomenclature used is that by Sanchíz (1998) for postcranial features, Roček et al (2022) for carpals, and Gómez and Turazzini (2016) for iliac features.

Position of the Specimen on the Slabs

The preserved portion of the specimen is 56 mm long (anterior end of ?omosternum to distal end of femora) on a 101x107 mm slab (M1) with its 69x63 mm partial counterpart (M2). The slab (M1) preserves a majority of the fossil, from base of the cranium to the femora (Fig. 2A, B). The partial counterpart (M2) preserves only the posterior region of the body and the hands (Fig. 2C, D). A majority of the bones are surrounded by a thin black veil interpreted as a skin impression, (see below; Fig. 2A, C). The bones of the specimen are preserved as (1) slightly crushed bony elements, (2) crushed and fragmentary bony elements; (3) imprint of the bone and (4) a mix of crushed bony element and imprint on both plates. As M1 is the main plate, the position and lateralization of the anuran skeleton are based on this slab. The imprint left by the humerus on the right side of M1 (see Fig. 2) preserves some detail distally (Fig. 2). Compared to the humeral imprint made from an extant *Pelophylax* (see Fig. S1), the fossa cubitalis and eminentia capitata are preserved as an imprint. Thus, we interpret the humeral imprint on IGR 144547 as visible in ventral view on M1. Hence, when the bone is preserved on M1, it is visible in dorsal view. Thus, IGR 144547 present an anuran specimen in dorsal view on M1, and in ventral view on M2. When only the imprint of the bone is preserved, it is visible in ventral view (on M1, opposite for M2). Hence, on M1, the left side of the specimen is visible on the left region of the plate, while it is preserved on the right region of the plate on M2.

Soft Tissues

The soft tissues surround most of the bones, except for the skull and part of the tibiofibula on both M1 and M2 (Fig. 2A, C). Although it is not well defined in most region, the preservation around the hands, femora, and cloacal region allows interpretation of this feature

as skin impressions. The body shape is hard to define on the torso, although it seems to widen at midlength (Fig. 2A). The body outline then narrows towards the cloacal region.

The skin around the shoulder and forelimb is poorly preserved. Skin around the hands is well preserved on both M1 and M2 (Fig. 2A, C). The left hand preserves the shape of the flesh around the digits, and the skin narrows towards the last phalanx of the digits. Around the femora, the skin is wider near its proximal margin, and progressively narrows distally until the end of both femora. On M2, small patches of skin imprints seem preserved around the left tibiofibula (Fig. 2C, D).

Osteological Description

IGR 144547 is an anuran skeleton missing its skull, its anterior vertebrae, most of the left elements of its pectoral girdle and most of its hindlimbs (Fig. 3). The skeleton is mostly articulated, but poorly preserved, in particular in the main body region (Figs. 2, 3).

Vertebral Column

General Comments—All vertebrae are badly preserved. Most of them are hollowed out, with only faint traces of centra and transverse processes preserved. Where bone is still present, the vertebrae are exposed in dorsal view, but the neural region has been crushed or eroded on all vertebrae, leaving the centrum exposed (Fig. 4). Presacral and sacral vertebrae are only preserved on M1. A single sacral vertebra is identified, while five presacral vertebrae are preserved. The atlas, second and third vertebrae are not preserved, due to a missing piece on M1 (Fig. 2A). IGR 144547 likely possessed eight presacral vertebrae.

Vertebra IV—The centrum and transverse processes of the fourth vertebra are preserved as crushed bone in dorsal view. The centrum is broken anteriorly. It connects posteriorly with the fifth vertebra and on its right lateral side with the sternum (Fig. 4A, B).

1
2
3 202 The base of the left transverse process shows that the processes extend slightly posteriorly.
4
5 203 They seem to expand distally (Fig. 4B).
6
7 204 **Vertebra V**—The centrum of the fifth vertebra is preserved as crushed bone in dorsal
8
9 205 view. It bears an anterior cotyle and a posterior condyle. It connects anteriorly to the fourth
10
11 206 vertebra and posteriorly to the sixth vertebra. A broken transverse process might be preserved
12
13 207 on the left lateral side of the centrum (Fig. 4B). It seems posteriorly oriented, like the
14
15 208 transverse processes of the seventh vertebra (see below), but it is broken from the centrum and
16
17 209 we cannot assess if it is its in-situ orientation.
18
19
20
21 210 **Vertebra VI**—Only the procoelous centrum of the sixth vertebra is preserved as
22
23 211 crushed bone in dorsal view. It connects anteriorly to the fifth vertebra and posteriorly to the
24
25 212 seventh vertebra. No transverse processes are preserved.
26
27
28 213 **Vertebra VII**— This vertebra has the longest preserved centrum (2.2 mm). It bears
29
30 214 anterior cotyle and a posterior condyle and is connected anteriorly to the sixth vertebra and
31
32 215 posteriorly to the eighth vertebra. The transverse processes are partially preserved. They are
33
34 216 crushed and are separated from the centrum. They are rather long and seem slightly posteriorly
35
36 217 oriented. However, the base of the left transverse process appears to be preserved (Fig. 4A, B)
37
38 218 and is laterally oriented.
39
40
41
42 219 **Vertebra VIII**—The last presacral is preserved throughout its centrum. Its centrum is
43
44 220 short (1.4 mm). It bears an anterior and a posterior cotyle. An amphicoelous posterior presacral
45
46 221 vertebra, with the remaining presacrals procoelous is diagnostic for a diplasiocoelous vertebral
47
48 222 column. A small remnant of the left transverse process is preserved on M1 (Fig. 4A, B). It
49
50 223 shows that the processes were straight and extended laterally.
51
52
53 224 **Sacral vertebra**—The sacral vertebra is only preserved on M1. Its centrum is
54
55 225 preserved as a hollow structure exposed dorsally (Fig. 4A, B). Nevertheless, its shows that an
56
57 226 anterior condyle and two posterior condyles are present. The centrum is short (2mm) and wider
58
59 227 than longer (2.6 mm width). The centrum seems to widen posteriorly (Fig. 4B). Both sacral
60

transverse processes are preserved on M1 as imprints (in ventral view) with bone fragments.

The right sacral transverse process is incomplete. The processes are oriented posterolaterally.

They barely expand distally and instead are slender rod-like structures. Thus, we interpret that

IGR 144547 as possessing a “Type IIA” sacrum (Emerson, 1979; Reilly & Jorgensen, 2011).

The sacral vertebra possesses a small diapophyseal expansion. Both sacral processes connect

distally with the ilium.

Urostyle—The urostyle is preserved on both M1 and M2. The proximal portion of the urostyle is preserved on M1 as crushed bone exposed in dorsal view on M1 and in ventral view on M2. The urostyle shaft is covered by sediment for most of its length on M1. On M2, the shaft is preserved as crushed bone (Fig. 2C). The urostyle is long (17 mm). It connects anteriorly to the sacral vertebra. Although poorly preserved, it is clear that two cotyles were present on its anterior surface. Most of the urostyle shaft is hollowed. The urostyle narrows progressively distally (Fig. 4C, D). Its distal end is crushed and covered by sediment on both M1 and M2. The urostyle seems to end slightly anterior to the acetabular region of both ilia (Fig. 2B, D). On M2, the anterior region of the urostyle is preserved as an imprint exposed dorsally, with a thin lamina of bone present medially (Fig. 4C). It suggests that a dorsal crest is present on the urostyle of IGR 144547 and extended for at least half of its length. However, we cannot assess the height of the dorsal crest, nor its total extension on the length of the urostyle.

Pectoral Girdle

Scapulae—The right scapula is preserved on M1 as an imprint with crushed bone. The left scapula is not preserved on M1. Scapulae are not preserved on M2. The scapula is elongate (7.81 mm length), with a shaft extended laterally (Fig. 5A, B). The shaft scapula expands distally, reaching its widest point at the suprascapular margin (Fig. 5B; 4.42 mm width). The latter is straight. The anterior and posterior margins are concave. Both margins lack laminae. The pars acromialis is mostly preserved as an imprint exposed in ventral view (Fig. 5A, B),

1
2
3 254 expect near the glenoid fossa. The pars acromialis is wide (3.3 mm), and part of this processus
4
5 255 is preserved as bone exposed in dorsal view in the glenoid region (see Fig. 5B). The glenoid
6
7 256 region is poorly preserved, with undefined crushed bony elements visible (Fig. 5B). As the
8
9 257 specimen is exposed dorsally, it suggests that most of the bony elements form the base of the
10
11 258 pars glenoidalis, distinct from the crushed pars acromialis (Fig. 5B). Thus, it is not possible to
12
13 259 assess the size of the pars glenoidalis and if the latter and the pars acromialis were separated by
14
15 260 a sinus glenoidalis.

16
17
18
19 261 **Clavicles**—Clavicles are only preserved on M1. The clavicle articulates with the
20
21 262 scapula and humerus (forming a part of the glenoid fossa). The right clavicle is partially
22
23 263 preserved as an imprint (exposed in ventral view; Fig. 5A), while the left clavicle is not
24
25 264 preserved. The extremitas medialis is not preserved. Thus, it is not possible to assess if the
26
27 265 latter articulated with the medial margin of the coracoid. The clavicle is slender and moderately
28
29 266 developed (5.89 mm preserved). Its shaft slightly arched. The glenoid region is partially
30
31 267 obscured by fragments of unidentified bone (Fig. 5A, B).

32
33
34
35 268 **Coracoids**—Both coracoids are preserved on M1 as imprints exposed in ventral view
36
37 269 (Fig. 2A). The right coracoid is almost complete. It forms part of the glenoid fossa laterally,
38
39 270 thus articulating with the clavicle and humerus. It also articulates medially with the left
40
41 271 coracoid. The coracoid is shorter (6.64 mm) than the scapula. The processus glenoidalis widens
42
43 272 laterally. It bears two distinct articular facets on its proximal surface. The anterior facet
44
45 273 articulates with the clavicle and the posterior facet received the humerus. The shaft is elongated
46
47 274 transversely and narrow. The processus epicoracoidalis is anteroposteriorly elongated. It is the
48
49 275 widest region of the coracoid (5.3 mm). The processus is flat and bears a convex medial margin
50
51 276 (Fig. 5B). It slightly extends anteriorly, but does not seem to form an anterior hook (as seen in
52
53 277 *Thaumastosaurus*; Laloy et al., 2013; Lemierre et al., 2021).

Both coracoids were likely in contact medially when accounting for the connecting cartilage of the coracoids (Ecker, 1889). This is characteristic of the firmsternal condition for the pectoral girdle (sensu Cope, 1864; Boulenger, 1886).

Sternum—The sternum is preserved as a crushed bone (exposed in dorsal view) within the space left by the vertebral column on M1 (Fig. 5B). The reconstruction shows that the bone is fully ossified (Fig. 5C). The bone is elongated anteroposteriorly (4.5 mm) and hourglass-shaped. Both anterior and posterior regions are wider than the shaft and the anterior region is wider than the posterior.

Omosternum?—A small, poorly preserved element is preserved anterior to the preserved medial region of the right clavicle on M1. It is very small (2.24 mm length) and crescentic (Fig. 5A, B). It likely represents around half of a bony element. A putative reconstruction indicates the element had an inverted Y-shape (Fig. 5C). The posterior end seems connected to the extremitas medialis of the clavicle. The remaining part of the bone is a slender stylet (Fig. 5B). The position and shape of this element is incompatible with a vertebral element. Thus, we tentatively interpreted this element as an incomplete omosternum. As for the non-overlapping coracoids, the presence of an ossified omosternum is diagnostic for a firmsternal pectoral girdle (sensu Boulenger, 1886).

Pelvic Girdle

Ilia—Both ilia are preserved on M1 and M2. M1 preserves most of the distal region and shaft of the ilia as flattened bones, exposed in medial view (Fig. 2A). Both distal ends are in contact with the posterior region of the sacral apophyses. The acetabular region is only preserved as an imprint exposed in lateral view of the left ilium on M1 (Fig. 2A). On M2, the left ilium is preserved in its acetabular region with most of the bone intact and exposed in lateral view (Fig. 2B, 6B). The right ilium has been broken in two. Its distal region on M1 is crushed and separated into two halves (Fig. 2A). The shape of the displaced sediment suggests

1
2
3 304 it could have been the result of damage during the splitting of M1 and M2 by the collector. The
4
5 305 acetabular region is displaced and covers part of the right femur and the dorsal acetabular
6
7 306 expansion of the right ilium on M2 (Fig. 2C). This part of the right ilium is preserved as a bone
8
9 307 exposed in medial view. The distal region of both ilia is preserved on M2 as imprints exposed
10
11 308 in medial view. The ilium is around 19.5 mm long. It is slightly longer than the urostyle. The
12
13 309 iliac shaft is slightly compressed laterally. The shaft bears a high dorsal crest (same height as
14
15 310 the iliac shaft) on its whole length (Fig. 2A), as seen on M1. The dorsal protuberance (‘tuber
16
17 311 superior’ in Bailon, 1999) is a large pyriform structure protruding laterally posterior to the
18
19 312 dorsal crest (Fig. 6B, C). The supracetabular fossa is well-developed (Fig. 6B, C). The dorsal
20
21 313 acetabular expansion is not fully preserved but seems short and oriented posteriorly (Fig. 6C).
22
23 314 The ventral acetabular expansion has a large ventral vector (Fig; 6B, C). Its preacetabular angle
24
25 315 is clearly acute (Fig. 6C). In medial view, there is no interiliac tubercle.
26
27
28
29
30
31
32

33 317 **Forelimbs**

34
35 318 **Humeri**—Both humeri are preserved only on M1. The proximal regions of both humeri
36
37 319 are preserved as both crushed bone and imprint, while the remaining of the diaphysis and distal
38
39 320 region is preserved only as an imprint exposed in ventral view. The right humerus is around 11
40
41 321 mm long. The proximal head of the right humerus is hard to identify, as the glenoid region is
42
43 322 poorly preserved (Figs. 5, 7D). The proximal region of the left humerus is preserved mostly as
44
45 323 crushed bone (exposed in dorsal view) but its outline is difficult to determine (Fig. 7A, B). No
46
47 324 crista ventralis is preserved. If present, the crista did not extend past the mid-diaphysis (region
48
49 325 preserved as a ventral imprint; Fig. 7C). The distal region of the right humerus is preserved as
50
51 326 an imprint exposed ventrally. The fossa cubitalis is shallow and slightly triangular shaped (Fig.
52
53 327 7C, D). The fossa does not extend on the diaphysis. The eminentia capitata (humeral ball in
54
55 328 Gómez & Turazzini, 2021) is wide and large (Fig. 7C, D). This structure is partially preserved
56
57 329 on the left humerus as eroded bone (thus visible in dorsal view; Fig. 7A) and on the right
58
59
60

humerus as an imprint (visible in ventral view; Fig. 7C). The eminentia capitata is not shifted laterally from the central axis of the diaphysis. The epicondylus radialis (lateral epicondyle) is partially preserved on the right humeral imprint (Fig. 7D). It is distinct from the eminentia capitata but does not extend distally past the humeral ball (Fig. 7C, D). The epicondylus ulnaris (medial epicondyle) is not preserved, hidden by the imprint of the radioulna (Fig. 7C).

Radioulnae—Only the right radioulna is preserved for its entire length on M1. Most of it is preserved as a ventrally exposed imprint (Fig. 7C). Only the distal region of the left radioulna is preserved on M1 as a ventrally exposed imprint. The distalmost portion of the left radioulna is preserved mostly as crushed bone on M2. The right radioulna (around 9 mm) is slightly shorter than the humerus (around 80% of total humeral length). The proximal region is articulated with the distal region of the humerus (Fig. 7C). The remaining imprint of the articulation did not preserve the shape of the proximal region. The diaphysis widens distally (Fig. 7D). It reaches its widest point at the level of the distal margin. Although badly crushed on M2, the presence of a shallow groove at mid-width is discernible (Fig. 7D). This groove allowed to discern both radial and ulnar articulation facets with the carpals (Fig. 7D).

Hands—Both hands are not fully preserved. The left hand preserves most elements, except for one phalanx on both M1 and M2 (Fig. 2A, C). Four digits are visible, with the following phalanx formula : 2–2–3–3. The right hand is poorly preserved on M1 (Fig. 2A)

Carpals—All carpals are preserved on both hands (Fig. 2A). Unfortunately, they are poorly preserved as crushed bones exposed in dorsal view. However, most of their shape has been preserved as imprint. Left and right carpals are preserved on M1 (Fig. 2A). Only the left carpals are preserved on M2 (Fig. 2C). The description is based on carpals from the left hand, preserved in dorsal view (see Fig. 8A). The carpals of the left hand seem preserved in anatomical position. Two rows are preserved.

The proximal row preserves three bones (left to right): the ulnare, radiale, and distal radiale (Fig. 8B). The ulnare (left lateral imprint) is roughly ellipsoid, slightly elongated

transversely (Fig. 8B). It articulates with the ulnare part of the articular surface of the radioulna, the radiale, and the distal ulnare (Fig. 8B). Three distinct articular facets are present on the ulnare. The posteromedial region of this element is slight protruding towards the radiale (Fig. 8B). This protrusion is interpreted as the fused intermedium (following Fabrezi and Alberch, 1996).

The radiale is the largest (both in width and length) of the proximal carpals. Its shape is difficult to discern but seems circular (Fig. 8). It articulates with the radial part of the articular surface of the radioulna, the ulnare, the distal radial element, and the distal carpalia III and IV (Fig. 8B). All four articular facets are concave (Fig. 8B).

The distal radial element is free. It articulates with the radiale, the distal carpale II, and the prepollex (Fig. 8B). The distal radial element is crescent-shaped, and its lateral margin is concave (Fig. 8B). Its proximal margin seems close to the radial (Fig. 8B). This is likely an artefact of preservation, as this region is difficult to visualize (Fig. 8A).

The distal row has three bones preserved: the distal carpal element (fused distal carpalia III, IV and ulnare element), the distal carpal II, and the prepollex (Fig. 8A). Distal carpalia III, IV and ulnare element (distal carpale V of Fabrezi & Alberch, 1996) are all fused into a single large bone (Fig. 8B). It contacts the ulnare, radiale, metacarpals III-V and the distal carpale II (Fig. 8B). The anterior margin bears two distinct articular surfaces for the ulnare and radiale (Fig. 8B). There is no indication that distinct articular facets are present on the posterior margin (Fig. 8B). The bone is crescentic, with a convex posterior margin (Fig. 8B).

Distal carpale II is a small circular element (Fig. 8B). It contacts the distal radial element, the prepollex, the distal carpal element, and the metacarpal II (Fig. 8B).

The prepollex is barely evident. Most, if not all, neobatrachians possess a prepollex composed of two distinct bones (Fabrezi & Barg, 2001). Unfortunately, only a single imprint is visible on the left hand of IGR 144547 (Fig. 8A). On its right hand this region is not preserved (Fig. 2B). As the two bones of the prepollex are often in contact (see Roček et al., 2022:fig.

2L) it is possible that they left a single imprint. The prepollex is small and triangular (Fig. 8B). It contacts the distal radial element, the distal carpale II, and the metacarpal II (Fig. 8B).

Metacarpals—Metacarpals II-V are all preserved on both hands on M1 (Fig. 2A, C). Shallow imprints of the left metacarpals are preserved on M2 (Fig. 2B). The right metacarpals are poorly preserved and poorly defined (Fig. 2A). Metacarpal II contacts the distal carpale II, and prepollex proximally and the phalanx I of II distally (Fig. 8B). It is one of the longest metacarpals (4.7 mm). Its proximal head is wider than its distal head. Both proximal and distal articular facet seems flat and straight (Fig. 8B). The bone is elongated, with a rather narrow diaphysis (Fig. 8B). Metacarpal III is shorter (4.5 mm) than metacarpal II. It contacts the distal carpale III proximally and the phalanx I of digit III distally. It is preserved with bone, with both proximal and distal heads are broken, while the diaphysis seems complete (Fig. 8A). As for metacarpal II, the diaphysis is elongated and narrow. The proximal head is wider than the distal head (Fig. 8B). The proximal and distal articular facets are flat and straight (Fig. 8B). Metacarpal IV is as long as metacarpal III (4.5 mm). It contacts the distal carpale IV proximally and the phalanx I of digit IV distally. As for metacarpal III, its distal and proximal heads are broken, and most of the diaphysis is broken as well (Fig. 8A). The proximal end bears a flat articular surface (Fig. 8B). The distal head is too damaged to assess the shape of its articular facet (Fig. 8B).

Metacarpal V is as long as metacarpal II (4.8 mm). It contacts the distal ulnare element proximally and the phalanx I of digit V distally. It is complete (Fig. 8B). Its proximal head is wider than its distal head. The articular facet of the proximal head is concave (Fig. 8B). The articular facet of the distal head is flat.

Phalanges—Phalanges are only preserved on the left hand, on both M1 and M2. Phalanx I is preserved on all digits (Fig. 8A). It is preserved as an imprint on digits II and V, and as a complete bone on digits III and IV. On digits II and IV, the phalanx is elongate (3.3 and 3.4 mm). On digit II, it is only preserved as a poorly defined imprint (Fig. 8A). On digit

1
2
3 408 IV, the preservation shows that the proximal head is wider than its distal head (Fig. 8B). Both
4
5 409 articular facets are flat. On digits III and V, phalanx I is shorter (2.8 and 2.4 mm), and the
6
7 410 proximal and distal heads are of the same width (Fig. 8B).

9
10 411 Phalanx II is also preserved on all digits. It is preserved as an imprint on digits II and V,
11
12 412 and as a complete bone on digits III and IV. For digits II and III, it is the terminal phalanx. It is
13
14 413 very short (1.5 mm). The phalanx narrows distally, before ending into a knob (Fig. 8B). On
15
16 414 digits IV and V, the phalanx II is connected distally to the phalanx III (Fig. 9B). It is shorter
17
18 415 than the phalanx I (2.6 and 2.2 respectively mm). Both proximal and distal heads are not
19
20 416 distinct from the diaphysis.

21
22
23 417 Phalanx III is preserved on digit IV only as an imprint (Fig. 8A). It is the terminal
24
25 418 phalanx for digits IV and V (missing on IGR 144547). It is identical to the terminal phalanx of
26
27 419 digits II and III. It is short (1.5 mm) and bears a knob on its distal end (Fig. 8B).

30 420

32
33 421 **Hindlimbs**

34
35 422 **Femora**—Both femora are preserved on M1 and M2. The left femur is incomplete on
36
37 423 M2. Both femora are preserved as a well-delimited imprints (exposed in ventral view) with
38
39 424 remnants of bone (Figs. 2A, C; 11A). Femora are long (22.1 mm) and slender. The proximal
40
41 425 head of the femur is badly preserved and mostly crushed near the acetabulum (Fig. 9B). No
42
43 426 crest nor flange is visible on its lateral and medial margins (Fig. 9B). The femur is slightly
44
45 427 sigmoid (S-shaped). No crest is visible on the femur shaft.

46
47
48 428 **Tibiofibulae**—Only the left tibiofibula is incompletely preserved on both M1 and M2.
49
50 429 The proximal region is preserved as an uncrushed bone, while the diaphysis is mostly
51
52 430 preserved as an imprint (exposed in ventral view). The distal region is not preserved (Fig. 9A,
53
54 431 B). The proximal head bears a shallow groove mid-width. This groove marks the separation
55
56 432 between the fused tibia and fibula (Fig. 9A, B). The tibiofibula is long (14 mm in length) and
57
58
59
60

straight. Slightly more than half of the tibiofibula appears to be preserved. Thus, the complete tibiofibula is probably slightly longer than the femur.

DISCUSSION

Taxonomic Attribution

Comparison to Extant European Anurans—The presence of a bicondylar sacro-urostyler articulation, a firmsternal pectoral girdle and a diplasiocoelous vertebral column are diagnostic for ranoid (Frost et al., 2006). Within Ranoidea, only natatanuran taxa are known in Europe in the Cenozoic (Roček, 2013). Furthermore, an ossified omosternum, if present, is considered a natatanuran synapomorphy (Frost et al., 2006; Lemierre et al., 2021). Within this clade, only Ranidae are known in Europe from the Oligocene (Sanchíz, 1998; Roček, 2013; Rage, 2016; Vasilyan, 2018). IGR144547 is similar to Ranidae in the following features: slender rod-like sacral apophyses, the eminentia capitata of the humerus is not shifted from the central axis of the humeral diaphysis and there is no crest on the femur.

Cenozoic and extant ranids from Western Europe have been only referred to two genera, *Rana* and *Pelophylax* (Duellman & Trueb, 1994; Sanchíz, 1998; Roček, 2013; Rage, 2016). During the twentieth and early twenty-first centuries, most authors considered the two genera synonymous (with *Pelophylax* sometimes considered a subgenus of *Rana*; Frost et al., 2006). In consequence, almost all known Cenozoic ranid from Europe were described as “*Rana*” (Sanchíz, 1998), regardless of their affinity towards the green water frogs (*Pelophylax* spp.) or brown water frogs (*Rana* spp.). In addition, osteological differences between extant European ranid and their Cenozoic counterpart are sometimes hard to find (Sanchíz, 1998). In addition, most of the European *Pelophylax* are grouped into the *Pelophylax* kl. *esculentus*, as hybridization is possible between species included into this complex (Lymberakis et al., 2007), and few (if any) osteological differences exists (Crochet et al., 1995). Thus, most of the taxa

erected since the nineteenth century are considered dubious (Sanchíz, 1998; Roček, 2013; Blain et al., 2023).

Osteological differences between *Pelophylax* and *Rana* are known for their postcranial elements (Sanchíz et al., 1993; Bailon, 1999) and cranial elements (Böhme, 1977; Bailon, 1999). The only element that allows a comparison is the ilium of IGR 144547, on which several character can be used to differentiate *Rana* and *Pelophylax* (Sanchiz et al., 1993; Bailon, 1999). IGR 144547 shares with *Pelophylax* kl. *Esculentus*: a large pyriform-shaped dorsal protuberance (Sanchíz et al., 1993; Bailon, 1999), a well-developed supracetabular fossa (‘dorsal preacetabular fossa’ in Sanchíz et al., 1993), a high dorsal crest anterior to the dorsal protuberance (Sanchíz et al., 1993); a high angle between the dorsal protuberance and the iliac shaft (~52° in IGR 144547; Sanchíz et al., 1993), and a small preacetabular zone (Sanchíz et al., 1993). Thus, we assign IGR 144547 to the genus *Pelophylax*, as a member of the complex *Pelophylax* kl. *esculentus*. Unfortunately, there is no current diagnostic apomorphies on the ilium between the different European species *Pelophylax* that would allow a more precise taxonomic assignment (Blain et al., 2015).

***Pelophylax* in the Oligocene of France**—As mentioned above, all extinct ranids from the Oligocene of Europe were described as *Rana* until recently. Thus, the most complete Oligocene ranid, “*Rana*” *aquensis* Coquand, 1845 has been referred to *Pelophylax* in the last decades (Sanchíz, 1998) on the basis of a similar osteology to *Pelophylax esculentus* (Sanchíz, 1998). However, there has not been any formal assignment to the genus, and the taxonomic validity of the taxon (i.e, as distinct from extant *Pelophylax* species placed under the *Pelophylax* kl. *esculentus*) has yet to be established (Sanchíz, 1998).

“*Rana*” *aquensis* is known by several subcomplete articulated specimens (Fig. 12A; Piveteau, 1927: fig. 4) from the late Oligocene of Southern France (Coquand, 1845; Piveteau, 1927; Sanchíz, 1998; Gaudant et al., 2018). The neotype (MNHN.F.AIX355) of “*Rana*” *aquensis* should be referred to the genus *Pelophylax* on the following features: a high and well-

developed dorsal crest on the ilium (Sanchiz et al., 1993; Bailon, 1999), a dorsal protuberance pyriform well-developed (Sanchiz et al., 1993), and a high angle ($\sim 42^\circ$) between the dorsal protuberance and the iliac shaft (Sanchiz et al., 1993; Bailon, 1999). Thus, we consider that all specimens assigned to “*Rana*” *aquensis* should be referred to the genus *Pelophylax*. However, we refrain from assessing the validity of *Pelophylax aquensis*, as this is beyond the scope of the study. *Pelophylax aquensis* has been considered closely related to the Miocene “*Rana*” *meriani* (Piveteau, 1927). Furthermore, a recent redescription of *Pelophylax pueyoi* (Blain et al., 2023) mentioned that the latter taxon (*P. pueyoi*) could be a subjective junior synonym of the Lower Miocene “*Rana*” *meriani* Meyer, 1852 (Meyer, 1860). Thus, a complete revision of the Oligo-Miocene *Pelophylax* is needed to assess if they represent distinct taxa, and if they could be differentiated from extant *Pelophylax* taxa.

Comparison of IGR 144547 to *Pelophylax aquensis*— IGR 144547 resembles *Pelophylax aquensis* in features of the ilium, that are diagnostic for *Pelophylax* kl. *esculentus*. The pectoral girdle of *Pelophylax aquensis* is poorly preserved (Piveteau, 1927), with only the cleithrum (“omoplate” in Piveteau, 1927) mentioned. Other specimens assigned to *P. aquensis* are known but have not been described (A.L. pers. obs). Thus, IGR 144547 does not differ from *Pelophylax aquensis*, but it cannot be distinguished from extant European *Pelophylax*. Hence, we refrain from any generic assignment for *Pelophylax aquensis*.

Paleobiogeography

The palearctic water frog *Pelophylax* ranges throughout Europe and Asia today (Duellman & Trueb, 1994; Chan & Brown, 2017). The divergence between the western (Europe) and eastern (Asia) lineages of *Pelophylax* has been estimated to have occurred around 35 Ma (Chan & Brown, 2017). The genus then spread throughout Europe and underwent a diversification event during the last 15 Ma (Lymberakis et al., 2007). However, the early diversification of the genus is almost unknown, as a single occurrence has been reported from

1
2
3 511 the early Oligocene of Germany (MP22; Sanchíz et al., 1993) and the genus is currently absent
4
5 512 from the early Oligocene sites of the Quercy Phosphorites (Rage, 2016). The attribution of IGR
6
7 513 144547 to *Pelophylax* and its geographical location, in northwestern France is very interesting.
8
9 514 It implies that the genus was present in northwestern Europe (from southern Germany to
10
11 515 northwestern France) no later than 5 Ma after its arrival in Europe. Thus, *Pelophylax*
12
13 516 apparently underwent a rapid dispersal throughout Europe during the early Oligocene. During
14
15 517 the late Oligocene, the genus is known throughout western Europe (Roček, 2013). This wide
16
17 518 and rapid dispersal was likely facilitated by the “Grande Coupure” extinction event. It is linked
18
19 519 to the Eocene/Oligocene transition (33.9 Ma) when a large turnover of the amphibian fauna
20
21 520 took place (Rage, 2016; Vasilyan, 2018), with the rise of “true” ranid (*Pelophylax*, *Rana*) in the
22
23 521 Oligocene (Roček, 2013; Rage, 2016). Thus, *Pelophylax* benefitted of the presence of
24
25 522 unoccupied ecological niches, and easily spread in Europe. It should be noted that this rapid
26
27 523 and vast dispersal might also reflect a sampling bias, in particular within the Quercy
28
29 524 Phosphorites (that represent most of anuran occurrences from western Europe during the early
30
31 525 Oligocene; Rage, 1984, 2016). Several possible ranids have been identified (Rage, 1984, 2016)
32
33 526 in the Quercy (MP22-23; Rage, 2016), but have not been studied since *Rana* and *Pelophylax*
34
35 527 became accepted as separated genera.

43

44 529 CONCLUSION

45
46 530
47
48
49 531 In conclusion, IGR 144547 represents one of the oldest known members of the
50
51 532 European *Pelophylax* kl. *esculentus*, and the oldest articulated specimen of *Pelophylax*
52
53 533 identified. We also suggest that ‘*Rana*’ *aquensis* should be included within *Pelophylax* kl.
54
55 534 *esculentus*. IGR 144547 resembles the holotype of *Pelophylax aquensis*, but a complete
56
57 535 revision of this taxon must be made before any assignment can be proposed. Our specimen
58
59 536 represents the first occurrence of *Pelophylax* in the early Oligocene of France. This occurrence
60

suggests a rapid dispersal of *Pelophylax* throughout western Europe during the Oligocene. This opportunistic frog genus likely benefited from unoccupied ecological niches and the decrease in anuran diversity following the “Grande Coupure”.

ACKNOWLEDGEMENTS

We wanted to thank O. Béthoux (CR2P, MNHN) for the access and loan of the portable light dome and formation on the use of the RTI softwares, V. Buffa (CR2P, MNHN) for the formation on the use of the light dome, D. Germain (CR2P, MNHN) for access to the MNHN specimens of *Pelophylax aquensis*. We also thank H.-D. Sues for his editorial work and two anonymous reviewers for their constructive reviews of the manuscript.

182x232mm (300 x 300 DPI)

Reconstruction of IGR 144547 in ventral view. Non-preserved elements are inferred from *Pelophylax esculentus*, gray areas represent non-preserved elements, scale bar represents 10 mm.

88x116mm (600 x 600 DPI)

Vertebral elements of IGR 144547. **A**, close-up on the vertebral region of IGR 144547 on M1, **B**, interpretative drawing of the same region, **C**, close-up on the urostyle of IGR 144547 on M2 and **D**, interpretative drawing of the same region. Scale bars represent 5 mm and light grey areas represent unidentified bony elements. **Abbreviations:** **IV**, fourth vertebra; **V**, fifth vertebra; **VI**, sixth vertebra; **VII**, seventh vertebra; **VIII**, eighth vertebra; **il**, ilium; **stp**, sacral transverse process; **sv**, sacral vertebra; **tp**, transverse process; **ur**, urostyle.

88x136mm (300 x 300 DPI)

Vertebral elements of IGR 144547. **A**, close-up on the vertebral region of IGR 144547 on M1, **B**, interpretative drawing of the same region, **C**, close-up on the urostyle of IGR 144547 on M2 and **D**, interpretative drawing of the same region. Scale bars represent 5 mm and light grey areas represent unidentified bony elements. **Abbreviations:** **IV**, fourth vertebra; **V**, fifth vertebra; **VI**, sixth vertebra; **VII**, seventh vertebra; **VIII**, eighth vertebra; **il**, ilium; **stp**, sacral transverse process; **sv**, sacral vertebra; **tp**, transverse process; **ur**, urostyle.

88x136mm (300 x 300 DPI)

Pectoral elements of IGR 144547. **A**, close-up on the right pectoral region of IGR 144547 on M1, **B**, interpretative drawing of the same region and **C**, reconstruction of the pectoral girdle in ventral view. Light gray area represents the glenoid region. . **Abbreviations:** **cl**, clavicle; **co**, coracoid; **glf**, glenoid fossa?; **hu**, humerus; **omst?**, putative omosternum; **par**, pars acromialis; **pecd**, processus epicoracoidalis; **pgl**, pars glenoidalis; **prgl**, processus glenoidalis; **sc**, scapula; **st**, sternum. Scale bar is 5 mm.

122x106mm (600 x 600 DPI)

Pectoral elements of IGR 144547. **A**, close-up on the right pectoral region of IGR 144547 on M1, **B**, interpretative drawing of the same region and **C**, reconstruction of the pectoral girdle in ventral view. Light gray area represents the glenoid region. . **Abbreviations:** **cl**, clavicle; **co**, coracoid; **glf**, glenoid fossa?; **hu**, humerus; **omst?**, putative omosternum; **par**, pars acromialis; **pecd**, processus epicoracoidalis; **pgl**, pars glenoidalis; **prgl**, processus glenoidalis; **sc**, scapula; **st**, sternum. Scale bar is 5 mm.

122x106mm (600 x 600 DPI)

Ilium of IGR144547. **A**, acetabular region of the left ilium exposed in lateral view on M2, **B**, proposed reconstruction of the acetabular region of the left ilium in lateral view and **C**, right ilium in exposed in medial view on M2. Scale bars represent 2 mm. **Abbreviations:** **acf**, acetabular fossa; **acr**, acetabular rim; **dae**, dorsal acetabular expansion; **dc**, dorsal crest; **dpm**, dorsal prominence; **dpt**, dorsal protuberance; **ish**, ilial shaft; **pz**, preacetabular zone; **saf**, supraacetabular fossa; **vae**, ventral acetabular expansion.

181x46mm (600 x 600 DPI)

Ilium of IGR144547. **A**, acetabular region of the left ilium exposed in lateral view on M2, **B**, proposed reconstruction of the acetabular region of the left ilium in lateral view and **C**, right ilium in exposed in medial view on M2. Scale bars represent 2 mm. **Abbreviations:** **acf**, acetabular fossa; **acr**, acetabular rim; **dae**, dorsal acetabular expansion; **dc**, dorsal crest; **dpm**, dorsal prominence; **dpt**, dorsal protuberance; **ish**, ilial shaft; **pz**, preacetabular zone; **saf**, supraacetabular fossa; **vae**, ventral acetabular expansion.

181x46mm (600 x 600 DPI)

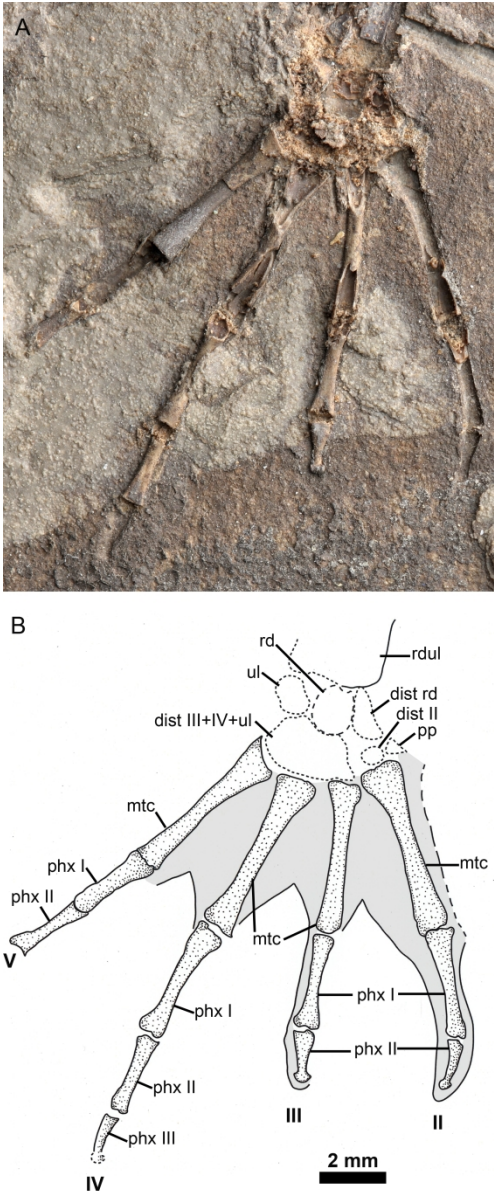

Forelimbs of IG144547. **A**, left humerus on M1, **B**, interpretative drawing of the same humerus, **C**, right forelimb on M1 and **D**, interpretative drawing of the same forelimb. Light gray area represents skin impressions, scale bars represent 5 mm. **Abbreviations:** **ec**, eminetia capitata; **dia**, diaphysis; **fc**, fossa cubitalis; **hb**, humeral ball; **raf**, radiale articular facet ; **recd**, epicondylus radialis.

88x132mm (600 x 600 DPI)

Forelimbs of IG144547. **A**, left humerus on M1, **B**, interpretative drawing of the same humerus, **C**, right forelimb on M1 and **D**, interpretative drawing of the same forelimb. Light gray area represents skin impressions, scale bars represent 5 mm. **Abbreviations:** **ec**, eminentia capitata; **dia**, diaphysis; **fc**, fossa cubitalis; **hb**, humeral ball; **raf**, radiale articular facet; **recd**, epicondylus radialis.

88x132mm (600 x 600 DPI)

Hand of IGR 144547. **A**, left hand on M1 and **B**, interpretative drawing of the same hand. Light gray areas represent skin impressions of the digits, scale bar represents 2 mm. **Abbreviations:** **dis rd**, distal radiale; **dist ul**, distal ulnare; **dist II**, distal carpale II; **dist III**, distal carpale III; **dist IV**, distal carpale IV; **mtc**, metacarpal; **phx I, II, III**, phalanx I, II, III; **pp**, prepollex; **rd**, radiale; **rdul**, radioulna; **ul**, ulnare.

88x216mm (600 x 600 DPI)

Hand of IGR 144547. **A**, left hand on M1 and **B**, interpretative drawing of the same hand. Light gray areas represent skin impressions of the digits, scale bar represents 2 mm. **Abbreviations:** **dis rd**, distal radiale; **dist ul**, distal ulnare; **dist II**, distal carpale II; **dist III**, distal carpale III; **dist IV**, distal carpale IV; **mtc**, metacarpal; **phx I, II, III**, phalanx I, II, III; **pp**, prepollex; **rd**, radiale; **rdul**, radioulna; **ul**, ulnare.

88x216mm (600 x 600 DPI)

Hindlimb of IGR 144547. **A**, right hindlimb on M1 and **B**, interpretative drawing of the same hindlimb. **Abbreviations:** **f**, femur; **tf**, tibiofibula. Dotted lines delimit skin impressions, scale bar is 5 mm.

88x107mm (600 x 600 DPI)

Hindlimb of IGR 144547. **A**, right hindlimb on M1 and **B**, interpretative drawing of the same hindlimb. **Abbreviations:** f, femur; tf, tibiofibula. Dotted lines delimit skin impressions, scale bar is 5 mm.

88x107mm (600 x 600 DPI)

FIGURE S1. Comparison between the imprint of the humerus of IGR 144547 and the humerus of *Pelophylax kl. esculentus*. **A**, imprint of a humerus of IGR 144547 on M1, **B**, imprint of a humerus of *P. kl. esculentus* in ventral view and **C**, imprint of the same humerus in dorsal view. Abbreviations: **ec**, eminetia capitate; **fc**, fossa cubitalis; **ols**, oleocranon scar; **recd**, epicondylus radialis.
