Arc volcanism arises from the release of fluids from descending slab, which lowers mantle solidus and enables melting. Mantle metasomatism plays an important role in magma production and arc volcanic activity at long spatial and temporal scales. However, the episodic eruption of individual volcanoes is generally thought to be primarily regulated by the evolution and recharge of crustal magma chambers, with no established link with mantle processes. Using high-resolution isotope time-series we show here a link between the most recent 1999-2016 eruptive activity of the Tungurahua volcano in Ecuador and the small-scale metasomatic enrichment of the magma source. During the eruption the average rate of magma production varies logarithmically with the degree of source enrichment. Such a correlation points to a major control of source enrichment on magma supply and eruptive activity, which is known so far only for basaltic shield volcanoes. The data also clearly show that the 1999-2016 eruption sequence ended because of the exhaustion of the enriched source during the very last weeks. Our findings suggest that the metasomatic fertilization of the mantle wedge over short spatial and temporal scales regulates magma production, and ultimately the last eruptive cycle of Tungurahua volcano. This is also a plausible mechanism to produce long-lasting eruptions at andesitic volcanoes.

47

Volcanoes are fed by vertically extensive magmatic systems rooted at the crust-mantle boundary¹. In arc setting, potentially large magma chambers may form atop these transcrustal systems and feed volcanic eruptions. Depth, temperature, and evolution of the shallow magma reservoirs are reasonably well constrained from phase equilibria experiments²⁻⁴, mineral chemistry⁵⁻⁷, and the temporal-compositional trends in the erupted magmas^{8,9}. Conversely, owing to the shallow magma chamber filter, the deep roots of arc magmatic systems are less well known. Thermal and physical models point these regions (the so-called "deep crustal hot zones") as the main place where arc magmas accumulate, differentiate and segregate from their source¹⁰. Magma production in the mantle and deep transfer processes are also increasingly thought to control the recharge and evolution of shallow magma chambers, and ultimately volcanic activity^{11,12}. Here we take advantage of the intense activity of Tungurahua stratovolcano (Ecuador) between 1999 and 2016, and the evidence from large scale syn-eruptive uplift of the edifice for continuous replenishment of the shallow magma chamber^{13,14} to constrain the compositional structure of the deep magma source by means of isotope analysis. We use regularly emitted glassy ash samples which, unlike scarce lavas and other eruptive products, provide a continuous record of magma composition and allow us to reconstruct the small-scale distribution of melts in the volcano source and their progressive extraction during the eruptive sequence. The high-resolution isotope record provides clues as to how deep processes control the secular activity of the Tungurahua volcano.

Tungurahua volcano

Tungurahua is an andesitic stratovolcano located in Ecuador along the eastern Andean Cordillera (Fig. 1a). Since 0.3 Ma the volcano produced mainly basaltic andesite and andesite, and occasionally dacite, with no compositional evolution through time^{15,16}. Since 1532 the

volcano showed a frequent activity, with main eruptive phases in 1641-1646, 1773-1781, 1886-1888, 1916-1918 and 1999-2016^{17,18}. Extensive multi-disciplinary study of the last 1999-2016 eruptive sequence allowed the identification of four stages (Fig. 2a): Stage 1 (1999-2005) started guite intensely with VEI2-3 eruptions in 1999 and 2001¹⁹ and the activity generally decreased trough time²⁰. Magma transfer and accumulation resulted in large-scale inflation of the volcano and passive SO₂ degassing^{21,13}. Between January and August 2006 (stage 2), the injection of volatile-rich andesitic magma into a partially degassed magma chamber triggered subplinian eruptions that produced Pyroclastic Density Currents (PDC) and lava flows²²⁻²⁴. Following the 2006 paroxysm, the activity generally decreased between 2007 and mid 2009 (stage 3), especially after the February 2008 event that produced PDCs and small lava flows. The activity became less continuous between 2010 and 2016 (stage 4), decreasing first until 2012, before increasing markedly from mid-2013 to mid-2014. Then the activity strongly decreased before a last burst between December 2015 and March 2016. The eruptive activity ended suddenly in March 2016 and only cold fumaroles occurred at the summit from 2017. The less continuous activity after 2009 was interpreted as sequential plugging of the system possibly due to lower magma feeding rate²⁵. Although few isotope data from 2006 lavas were previously reported¹⁶, no study so far investigated isotope variations over the eruptive sequence, and generally the role of magma source composition. In particular, the deep source processes responsible for the onset and sudden end of this major eruptive episode remain poorly known. Between November 1999 and March 2016, Tungurahua ash samples were collected monthly to daily at the Choglontus station located below the main plume dispersion axis (W-SW) and far from main roads (Figs. 1b and 2b). Ninety-eight samples were analyzed for Pb and Sr isotope compositions (see Methods).

Lead and strontium isotope compositions of ash samples are reported in supplementary Table S1 and plotted against time in Fig. 3. The isotope compositions of ashes show rapid variations, but no clear temporal trend over the 1999-2016 eruption sequence, beyond the decrease of 87 Sr/ 86 Sr and 206 Pb/ 204 Pb, and the increase of 207 Pb/ 206 Pb during the last six months. The variations of raw isotopic ratios have no simple interpretation because each isotope ratio is influenced by more than two sources in Ecuador volcanism²⁶. However, the three isotope dimensions of the Pb system can be used to disentangle the different magma sources. Three main components contribute to the Pb isotopic composition of Tungurahua magmas¹⁶: (1) Depleted mantle. (2) A chemically enriched component derived from slab dehydration and/or melting. This component may occur as pyroxenite veins in the sub-arc mantle^{27,28}, or as later products of melt-rock reactions, such as clinopyroxene-and/or amphibole-bearing cumulates in the lower crust^{29,30}. This component will be referred to as enriched deep component given the uncertainty on its exact nature and location. It will also be called "fertile" due to its lower melting point. (3) Upper continental crust assimilated by mantle derived magmas. The later crustal component must itself include a radiogenic and an unradiogenic end-member to account for the large Pb isotope heterogeneity of basement rocks¹⁶. Although magma components mix at the liquid state, mass balance calculation and results will refer to parental rocks to circumvent the uncertainty related to melting. All compositions used in the model are given in Table 1 (see Methods). The mass-balance equations were solved in three-dimension ²⁰⁴Pb-normalized isotope space using matrix formulation (see Methods).

118

119

117

Magma source components versus eruptive activity

The cumulative volume of magma and derived magma production rate (see Methods) are plotted against time (Fig. 4a, b) together with the computed mass fractions of the four source components (Fig. 4c-f). A major observation is that the depleted mantle and the enriched deep component show antithetic temporal variations related to the main eruption stages. For instance, the contribution of the enriched deep component peaked during the 2006 eruption paroxysm (up to 70%), before decreasing between 2007 and mid-2009 (Stage 3), down to 23% in June 2009, as the eruption activity decreased (Fig. 4d). The contribution of the enriched deep component increased again during early stage 4, reaching 60% in August 2012 while the activity had become again nearly continuous (between November 2011 and September 2012). It stayed elevated (about 50%) during the following period of high activity (mid-2013 - mid-2014) before decreasing at the end of the eruptive sequence, in particular during the last six months (Fig. 4d). Remarkably, the fraction of the enriched deep component was the lowest (12.6%) during the very last weeks of the sequence (February 27 to March 14, 2016), strongly suggesting that the 1999-2016 eruption sequence of Tungurahua ended because of the exhaustion of the enriched component in the mantle source. A corollary is that the whole 1999-2016 eruption sequence must result from the melting of a small fertile domain, whether in the crust or in the mantle. On the other hand, the highly correlated (r^2 =0.88) contributions of the two crustal components do not show clear temporal trends, but generally more variability during the first two years of the sequence, and between 2006 and 2009 (Fig. 4e, f). To evaluate statistically the apparent relation between magma source composition and eruption activity, we have analyzed the correlations between the deep source components and the rate of deep magma supply. Figure 5 shows that magma supply rate correlates positively (r^2 =0.61) with the enriched deep component and negatively (r^2 =0.62) with the depleted mantle component. Moreover, it is important to note that linear variations of

magma source composition result in logarithmic variations of magma production rate, demonstrating that even small variations of mantle fertility have a strong influence on magma supply and eruptive activity. For example, over the course of the 1999-2016 eruption sequence, a factor of 3 variation of the enriched component resulted in a factor of 300 variations of magma production rate (Fig. 5a). Although the correlations shown in Fig. 5 are highly significant, they nevertheless show some scatter of the data. This scatter most likely results from magma chamber and conduit processes occasionally uncoupling source and surface processes. Such decoupling is especially apparent at the very beginning of the eruption (1999-2001) (Fig. 4 b-d), where high magma production rate likely resulted from the depressurization of the magma reservoir, whereas magma composition likely reflected mixing between old unerupted magmas from the last 1916-1918 eruption stored in the shallow reservoir and new magmas rising from the mantle. During stage 2 and 3, the tight coupling between eruption activity and source composition are consistent with steady-state supply and open-vent conditions. Conversely, during stage 4 the increase of the fertile component predated the peak of surface activity (July 2013 – April 2014) possibly because the plugging of the conduit²⁵ increased magma storage and mixing before eruption.

Implications

Arc volcanism arises from the input of slab fluids that changes mantle composition, lowers its solidus and enables partial melting. In Ecuador, the variations of mantle metasomatism in space and time are responsible for the compositional variations of magmas across^{26,30-32} and along^{26,28} the arc, and the chemical evolution of long-lived volcanic complexes^{33,34}. Using high-resolution Pb isotope time-series we show here for the first time a tight link between small scale metasomatic enrichment of the magma source, and the short-term eruptive activity of

a volcano. This link is especially apparent after the early draining of the shallow magma reservoir (1999-2001 magma surge) once the volcano is directly fed from the deep magma source (Fig. 4). Such a link between magma source fertility and eruptive activity is known for basaltic shield volcanoes, which are connected to their mantle sources by relatively simple feeding systems^{35,36}, but is unexpected for Tungurahua stratovolcano that includes several zones of magma storage between 1 and 15 km depth^{13,14,22,37,38}. In the context of continental arc volcanism, the direct connection between mantle or lower-crust and eruption at the surface has two major requirements. First, a process must convert the necessarily slow melting processes into high melt flux to the shallow magma chamber. Reactive melt transport has been shown to meet this requirement beneath mid-ocean ridges³⁹ as well as in arc setting⁴⁰. This process is fundamentally based on the chemically unstable nature of primary melts. In arc setting, primary melts with high silica and water contents dissolve olivine and crystalize pyroxene⁴¹. Pyroxene is subsequently replaced by amphibole as the melt-rock reaction proceeds near the mantle-crust boundary²⁹. The dissolution-precipitation reactions increase locally the porosity and permeability of the mantle and lead to the formation of melt channels. Keller and Katz⁴⁰ showed that dissolution of fertile material and magma transport in such channels are enhanced by up to an order of magnitude. Very importantly, the formation of melt channels is an unstable process that bridges the gap between the slow melting of the mantle and the fast melt extraction required to feed sustained volcanic eruptions. Rawson et al.⁴² suggested that reactive channels are likely to develop in the distal parts of the mantle wedge where more stable thermal and rheological conditions prevail. The location of Tungurahua volcano along the eastern Cordillera, 330 km away from the subduction trench, could favor the development of reactive melt channels. The high magma productivity of Tungurahua volcano might also be related to its location above a major fault

in the subducting plate (The Grijalva Fracture Zone) (Fig. 1a), because serpentinized peridotites exhumed near fracture zones may deliver large amounts of volatiles to the sub-arc mantle and enhance flux melting⁴³. The second requirement is that the inflow of mantle derived magmas is not totally absorbed by the magma storage system in the crust, so that part of the magma flow directly feeds the eruptions. In support of such a process, large-scale uplift of the Tungurahua edifice between 2003 and 2014 indicates continuous replenishment of the magma reservoir during the eruption sequence, with slightly more than half of the magma supplied to the reservoir reaching the surface 13,14. Thus, Tungurahua seems to belong to the few stratovolcanoes from the Central and South American arcs that are directly connected to their mantle source, together with Irazu volcano in Costa Rica⁴⁴ and Ollagüe volcano in Chile⁴⁵. In such a situation, extensive crustal contamination of Tungurahua magmas^{16,26} is at first glance paradoxical because crustal assimilation is generally thought to be related to magma storage and differentiation in the crust. The extensive contamination of Tungurahua andesitic magmas can be reconciled with the evidence for short residence time in the crust if the magmas are superheated during rapid ascent^{45,46}. In support of this hypothesis, the absence of amphibole in Tungurahua andesites, together with thermometric and experimental constraints suggest that the magmas evolved at temperatures higher than 950-1000 °C^{22,37}. The time scale of magma ascent is not constrained here, but the residence time of magma in the reservoir must be comparable to the time scale of geochemical fluctuations⁴⁷, on the order of years (Fig. 3). The view that emerges for Tungurahua is that of a more dynamic magmatic system compared to the deep crustal hot zones¹⁰ which require timescale of 10⁵–10⁶ years for thermal incubation at depth, and 10–10³ years for magmatic differentiation from basalt to andesite. One possible solution is that the trans-crustal plumbing system is a much more dynamic

environment than expected, with probably "active" zones with rapid magma ascent and other zones dominated by magma accumulation and differentiation. In this frame, Tungurahua is a good candidate to join the growing family of arc volcanoes, where seismic tomography⁴⁸, volatiles diffusion along crystal embayments⁴⁹, and Ra-Th isotope disequilibria⁵⁰ indicate ultrafast magma ascent in well-developed melt channels. A major outcome of this study is that eruption of the Tungurahua volcano requires at least 12% of fertile lithology in its source. Below 12%, melt production is likely too low to sustain magma eruption at the surface, as illustrated by the exhaustion of the fertile component a few weeks before the end of the 1999-2016 eruption sequence. Conversely, when the fraction of the fertile lithology reaches 60-70%, reactive channeling instabilities allow high melt supply to the volcano, and trigger eruption paroxysm, such as in 2006. In support of such process, magma production increases logarithmically with the degree of source enrichment (Fig. 5). The nature and location of the fertile source lithology (i.e., the enriched deep component) remain uncertain, although its isotopic signature requires a genetic link with the subducting oceanic crust. In any case, the fact that the fractions of the enriched deep component and the depleted mantle are strictly complementary (Fig. 4c,d) points to a mantle origin for the isotopic signal correlating with volcanic activity. In such situation, our preferred interpretation is that metasomatic fertilization of the mantle wedge over short spatial and temporal scales regulates magma production rates and ultimately the secular activity of the volcano. Small-scale variations of mantle metasomatism in southern Ecuador is independently evidenced by olivine-hosted melt inclusions²⁸, and could be related to variations of the thermal structure and composition of the subducting plate in the vicinity of the Grijalva Fracture Zone. This work confidently resolves a link between the short-term activity of an arc volcano and the small-scale heterogeneity of its magma source. This observation leaves some open

questions regarding the geometry of the melting source and how melting and melt extraction occur. For instance, the episodic activity of arc volcanoes could reflect the melting of individual fertile veins forming some kind of fractal tree in the mantle wedge. In such case, the spatial distribution and the size of the veins, and the re-organization of melt channels driven by the slow decompression of the mantle, will control melt production and volcano supply. Alternatively, if each volcano is fed by a main melt channel in the mantle wedge⁵¹, short-term variations in fluid delivery from the slab and related flux melting are expected to govern melt production and volcano supply. On a more practical point of view, the results of this work suggest that volcano monitoring techniques should be designed to track the deeper process of the magmatic plumbing system. For instance, monitoring the isotopic composition of juvenile ashes during a long-lived eruption, or an eruption sequence, would provide information on how the fertility of the magma source evolves as the eruption proceeds. Such information could be used to forecast eruption paroxysm, major changes of activity, or eruption end. The volatility of Pb in magmatic systems also raises the possibility to probe the hidden magmatic evolution of quiescent volcanoes from the Pb isotope composition of volcanic gases⁵².

Samples. Ash fallouts were sampled using ash collectors before 2010 and an ashmeter device subsequently⁵⁴. The 1999-2016 ash samples are dominantly juvenile. They include black and brown scoria, 100 to 600 μ m in size, larger beige pumices (1000 to 5000 μ m) and glass shards. Ashes matrix is glassy to micro-crystallized and shows a uniform mineralogical assemblage (plagioclases + orthopyroxenes + clinopyroxenes + Fe-Ti oxides \pm olivines). These observations are consistent with previous descriptions^{22,23,53}.

Analytical methods. All chemical analyses were performed at the Laboratoire Magmas et Volcans (Clermont-Ferrand, France) between 2018 and 2020. Lead and Sr isotope compositions were measured on 5 mg of juvenile glassy fragments that were hand-picked under a binocular microscope and washed in deionized water. Following sample dissolution with HNO₃-HF, Pb and Sr were separated using polyethylene columns filled with 50 μL of Sr.Spec extraction chromatographic material 55 . Full procedural blanks were 2.7 \pm 1.1 ng for Sr (n= 13) and 19 ± 15 pg for Pb (n=9), which are negligible compared to the amounts of Sr (2.1-3.7 µg) and Pb (40-75 ng) extracted from the ash samples. Lead isotope compositions were measured on a Thermo Fisher Scientific Neptune Plus MC-ICP-MS coupled to an Aridus II desolvating nebulizer system. The Pb instrumental mass fractionation was corrected during measurement by doping the Pb solutions with the Tl NBS997 standard. The NBS981 standard was measured between every two samples to correct Pb ratios for instrumental drift and the slight difference in mass fractionation between Pb and Tl. Data were normalized to the NBS981 standard using the values of Todt el al. 56 (206 Pb/ 204 Pb= 16.9356, 207 Pb/ 204 Pb= 15.4891, ²⁰⁸Pb/²⁰⁴Pb= 36.7006). Repeated analysis of the NBS981 standard every two samples yielded average intra-session reproducibility of 115 ppm (2 S.D.) for the 206 Pb/ 204 Pb ratio. Strontium isotope compositions were measured on a Thermo Fisher Scientific Triton Thermal Ionization Mass Spectrometer (TIMS) and were corrected for mass fractionation using 86 Sr/ 88 Sr=0.1194. Repeated measurement of the NBS SRM 987 standard during the course of the study yielded 87 Sr/ 86 Sr=0.710232 \pm 8 (2 S.D.). Sample data were renormalized to the accepted value of 0.710245. Repeated measurement (duplicate dissolution) of rock reference materials yielded 87 Sr/ 86 Sr= 0.705004 \pm 14, 206 Pb/ 204 Pb = 18.756 \pm 0.005, 207 Pb/ 204 Pb = 15.615 \pm 0.004, 208 Pb/ 204 Pb = 38.708 \pm 0.026 for BCR2 basalt (n=5), and 87 Sr/ 86 Sr= 0.703532 \pm 13, 206 Pb/ 204 Pb = 18.301 \pm 0.005, 207 Pb/ 204 Pb = 15.536 \pm 0.007, 208 Pb/ 204 Pb = 38.249 \pm 0.024 for JA-1 andesite (n=6).

Mixing model. The compositions of the four end-member components used in the mixing model are given in Table1.

Table 1

	Depleted Enriched		High U/Pb	Low U/Pb		
	mantle	deep component	Pb poor crust	Pb rich crust		
		(arc pyroxenite)				
Pb (ppm)	0.018	0.06	9	17		
²⁰⁶ Pb/ ²⁰⁴ Pb	18.40	19.10	19.20	18.79		
²⁰⁷ Pb/ ²⁰⁴ Pb	15.50	15.56	15.72	15.66		
²⁰⁸ Pb/ ²⁰⁴ Pb	38.00	38.70	39.22	38.60		

The Pb concentration of the depleted mantle is from ref. ⁵⁷. The Pb content of the enriched deep component is assumed to be as in clinopyroxenes crystalizing early in arc magmatism²⁹.

Lead concentrations of basement rocks are from Nauret et al. 16 . Lead isotopic compositions of the four components are also from Nauret et al. 16 , with slight modification of the crustal compositions. This fine tuning is needed to model the most contaminated samples with high 207 Pb/ 204 Pb. The Andean continental crust being highly heterogeneous, it is possible that the crustal rocks assimilated during the 1999-2016 eruption of the Tungurahua volcano are not exactly the same as the five basement samples analyzed by Nauret et al. 16 . The mass fractions (x) of the four components are quantified in the 206 Pb/ 204 Pb $-^{207}$ Pb/ 204 Pb $-^{208}$ Pb/ 204 Pb isotope space by solving the mass balance equation system:

$$Pb_1.x_1.[(64)_s-(64)_1] + Pb_2.x_2.[(64)_s-(64)_2] + Pb_3.x_3.[(64)_s-(64)_3] + Pb_4.x_4.[(64)_s-(64)_4] = 0$$

506
$$Pb_1.x_1.[(74)_s-(74)_1] + Pb_2.x_2.[(74)_s-(74)_2] + Pb_3.x_3.[(74)_s-(74)_3] + Pb_4.x_4.[(74)_s-(74)_4] = 0$$

507
$$Pb_1.x_1.[(84)_s-(84)_1] + Pb_2.x_2.[(84)_s-(84)_2] + Pb_3.x_3.[(84)_s-(84)_3] + Pb_4.x_4.[(84)_s-(84)_4] = 0$$

$$508 x_1 + x_2 + x_3 + x_4 = 1$$

where (64), (74) and (84) are for ²⁰⁶Pb/²⁰⁴Pb, ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb isotope ratios, respectively; Pb is for lead concentration, subscript S is for sample, and subscripts 1-4 are for the four mixing components reported in Table 1. The equation system can be written as the matrix product:

Pb ₁ .[(64) _s -(64) ₁]	Pb ₂ .[(64) _s -(64) ₂]	$Pb_3.[(64)_s-(64)_3]$	Pb ₄ .[(64) _s -(64) ₄]		X ₁		0	
Pb ₁ .[(74) _s -(74) ₁]	Pb ₂ .[(74) _s -(74) ₂]	Pb ₃ .[(74) _s -(74) ₃]	Pb ₄ .[(74) _s -(74) ₄]	•	X ₂	=	0	
Pb ₁ .[(84) _s -(84) ₁]	Pb ₂ .[(84) _s -(84) ₂]	Pb ₃ .[(84) _s -(84) ₃]	Pb ₄ .[(84) _s -(84) ₄]		X 3		0	
1	1	1	1		X 4		1	
				I	ı		ı	

516 or: 517 518 A • B = C 519 520 the solution matrix B is obtained from 521 $B = A^{-1} \bullet C$ 522 523 where A⁻¹ is the inverse matrix of A. 524 525 We stress that the temporal trends inferred from the model (Fig. 4) do not depend on the 526 precise composition of the end-member components used (Table 1). In support of this idea, consistent trends can be inferred from the raw ²⁰⁷Pb/²⁰⁶Pb and ²⁰⁷Pb/²⁰⁴Pb ratios (Fig. 3b,d), 527 which dominantly record mantle composition and crustal processes, respectively^{16,26}. 528 529 530 531 Rate of deep magma supply. The cumulative volume of magma was determined using ash fallout data from ref. ²⁰ for the 1999-2004 period, and ref. ⁵⁸ for the 2006-2014 period. Ash 532 533 volumes were converted into magma volumes assuming the density of magma is 2.5 times 534 that of ash deposit. For the August 2006 paroxysmal eruption, we used the complete mass quantification of ref. ⁵⁹. For the 2014-2016 period, our ash fallout measurements correspond 535 to 9.4×10⁴ m³ (09/03/2014-06/22/2015), 8.7×10⁴ m³ (06/22/2015-09/05/2015), 8.7×10⁵ m³ 536 537 (09/05/2015-12/08/2015) and 4.2×10^5 m³ (02/26/2016-03/15/2016) of magma (B.B.

at:

volcan). We also included in the calculation the 2010 and 2014 lava flows (1x10⁶ m³ each according to ref. ⁶⁰ and B.B. unpublished data) and the accumulation of ballistic material in the summit crater (3.4×10⁶ m³ between 2008 and 2012 and 0.8×10⁶ m³ between 2012 and 2016, which translates into 2.1×10⁶ m³ and 0.5×10⁶ m³ of magma, respectively, according to ref.⁵⁹). Summit crater data are from D. Yaguana 2020 engineering thesis (http://bibdigital.epn.edu.ec/handle/15000/21245). The cumulative volume emission curve was built with a time resolution of one point per month (Fig. 4a). The rate of deep magma supply (Fig. 4b) was estimated by calculating the slope of the cumulative volume emission curve over a moving two-year window (linear regression through 24 data points). A two-year window was selected because it corresponds to the timescale of source component fluctuations (Fig. 4c,d). Such a relatively wide time-window is expected to smooth monthly variations of shallow magma supply, which has varied by a factor of 10⁶ over the course of the 1999-2006 eruption²⁰. The calculated rate of magma supply was assigned to the middle of the time window.
