ABSTRACT

Volatile organic molecules and a complex organic refractory material were detected on the Moon and on lunar samples. The Moon's surface is exposed to a continuous flux of solar UV photons and fast ions, e.g. galactic cosmic rays (GCRs), solar wind (SW), and solar energetic particles (SEPs), that modify the physical and chemical properties of surface materials, thus challenging the survival of organic compounds. With this in mind, the aim of this work is to estimate the lifetime of organic compounds on the Moon's surface under processing by energetic particles. We performed laboratory experiments to measure the destruction cross section of selected organic compounds, namely methane (CH₄), formamide (NH₂CHO), and an organic refractory residue, under simulated Moon conditions. Volatile species were deposited at low temperature (17 - 18 K) and irradiated with energetic ions (200 keV) in an ultra-high vacuum chamber. The organic refractory residue was produced after warming up of a CO:CH₄ ice mixture irradiated with 200 keV H⁺ at 18 K. All the samples were analyzed in situ by infrared transmission spectroscopy. We found that destruction cross sections are strongly affected (up to one order of magnitude) by the dilution of a given organic in an inert matrix. Among the selected samples, organic refractory residues are the most resistant to radiation. We estimated the lifetime of organic compounds on the surface of the Moon by calculating the dose rate due to GCRs and SEPs at the Moon's orbit and by using the experimental cross section values. Taking into account impact gardening, we also estimated the fraction of surviving organic material as a function of depth. Our results are compatible with the detection of CH₄ in the LCROSS eject plume originating from layers deeper than about 0.7 m at the Moon's South Pole and with the identification of complex organic material in lunar samples collected by Apollo 17 mission.

1. Introduction

Between 1969 and 1972, Apollo missions brought back 382 kg of rocks from the lunar surface; H₂O and other volatile species have been the subject of intense study because they offer important constraints on the Moon's origin and evolution, as well as for evaluating potential future human exploration (e.g. Jones et al., 2020, 2021; McLain et al., 2021; Clendenen et al., 2022). Whether significant amounts of organic compounds were present was one of the most carefully researched questions following the gathering of Apollo lunar samples. Interest in the nature of lunar organic matter has continued to the present day, with indigenous complex organic material recently identified for the first time in Apollo 17 samples. Indeed, Thomas-Keptra et al. (2014) has revealed that non-terrestrial, complex organic matter is intimately associated with glass beads collected during the mission. C-rich micrometeorites and interplanetary dust particles (IDPs) are described as contributors to the abiotic organic inventory of the early Earth and possibly of the lunar regolith. Any material placed or exposed on the surface of bodies without a substantial atmosphere and a global magnetic field is subject to weathering by galactic cosmic rays (GCRs), solar wind (SW), and solar energetic particles (SEPs) (e.g. Glotch et al., 2019). Crites et al. (2013) showed that GCR protons provide enough energy to stimulate chemistry over the time available for ices to be retained in lunar cold traps (1–2 Ga); on the one hand, dose rate calculations indicate that organic synthesis is plausible well within the age of the lunar polar cold traps and that organics detected at the poles of the Moon may have been produced in situ. On the other hand, several laboratory investigations showed that organic matter can be destroyed by exposure to energetic ions (e.g. Gerakines et al., 2012; Gerakines and

Radiation-induced destruction of organic compounds on the Moon

58 Hudson, 2013; De Sanctis et al., 2023). In light of this, the focus of this paper is on the survival of organic compounds
 59 to energetic ions on the Moon's surface. For our study, we have selected some representative organic samples, namely
 60 methane (CH₄), formamide (NH₂CHO) and an organic refractory residue. Many factors have influenced the choice
 61 of chemicals to employ: CH₄ is the simplest hydrocarbon and a widely spread molecule along the line of sight to star
 62 forming regions (e.g. Cruikshank et al., 2000; Grundy and Buie, 2001; Fulvio et al., 2010; Boogert et al., 2015; Barucci
 63 and Merlin, 2020). In addition, proof of the presence of CH₄ was found on the Moon, during LCROSS mission when
 64 the lunar south pole crater Cabeus was impacted by a spent Centaur rocket which caused debris, dust, and vapor to be
 65 ejected (Colaprete et al., 2010); from spectral fits, the authors derived a relative abundance of 0.65% for CH₄ w.r.t. to
 66 H₂O.

67 Formamide (NH₂CHO) is a molecule that belongs to the amide family and includes a peptide bond. Several studies
 68 showed that it can act as a precursor in the formation of amino and nucleic acids (Saladino et al., 2005, 2009, 2012; Pino
 69 et al., 2015), making it one of the possible players in pre-biotic chemistry. NH₂CHO has been observed in cometary
 70 comae and on the comet 67P/C-G during the Rosetta mission (Bockelée-Morvan et al., 2000; Goesmann et al., 2015).
 71 In particular, Goesmann et al. (2015) reported that the abundance of this molecule can be as high as 1.8% w.r.t. water.
 72 Furthermore, Schutte et al. (1999) and Raunier et al. (2004) reported a tentative detection of solid formamide in the
 73 line-of-sight of young stellar objects observed with the Infrared Space Observatory-Short Wavelength Spectrometer
 74 (ISO-SWS).

75 An organic refractory residue is an organic-rich material left over after irradiation of simple ices containing C-
 76 bearing species (e.g. Palumbo et al., 2004; Baratta et al., 2015; Accolla et al., 2018; Baratta et al., 2019). Analysis by
 77 infrared spectroscopy and mass spectrometry indicate that organic refractory residues contains thousands of organic
 78 compounds, including species of relevance for Astrobiology, such as amino acids, sugars, and nucleobases (e.g. Danger
 79 et al., 2013; Meinert et al., 2016; Materese et al., 2017; Accolla et al., 2018; Nuevo et al., 2018; Urso et al., 2020). **As**
 80 **discussed by Baratta et al. (2019) organic refractory residues obtained after ion irradiation of simple ices can be**
 81 **considered analogues of organic matter in space. Indeed residues produced in laboratory from ion irradiation of**
 82 **simple ice mixtures are good spectral analogue of extraterrestrial organic material detected in micrometeorites**
 83 **and interplanetary dust particles (IDPs) (Baratta et al., 2015; Potapov et al., 2022).**

84 **The aim of our experimental investigations is to consider different ice mixtures or organic refractory samples**
 85 **in order to constrain the range of destruction cross section values of relevant compounds. In the experiments**
 86 **here presented, CH₄ is mixed with N₂. The idea is to mix CH₄ in an H-poor matrix to reduce as many backward**
 87 **reactions as possible; these would, indeed, reform CH₄. On the other hand additional destruction pathways**
 88 **which include N could take place to better simulate the presence of CH₄ in trace amounts. Similarly, we**
 89 **investigated the case of an organic-rich environment (pure NH₂CHO) and the case of NH₂CHO diluted in an**
 90 **inert matrix. These extreme cases, none of which is realistic, allow us to measure the upper and lower limit of**
 91 **the destruction cross section.** Furthermore, N₂:CH₄ mixtures and the organic residues are irradiated with different
 92 ions, namely H⁺, He⁺, and N⁺, at 200 keV to take into account the most abundant species in SEPs and to investigate
 93 any difference due to the impinging projectile.

94 The manuscript is organized as follows: in §2 the experimental set-up and procedures are described, in §3 the
 95 experimental results are presented and their relevance is discussed in §4.

96 2. Materials and Methods

97 The experiments presented here have been conducted in the Laboratory for Experimental Astrophysics (LAsp) at
 98 INAF - Osservatorio Astrofisico di Catania (Italy). All the experiments are performed in an ultra-high vacuum (UHV)
 99 chamber ($P < 10^{-9}$ mbar), shown in Fig. 1. Ice samples are accreted on an infrared transparent substrate (KBr) placed
 100 in thermal contact with the final tail (cold finger) of a closed-cycle helium Cryocooler (CTI) that allows temperatures
 101 to vary between 17 and 300 K. Gas phase species, except than formamide, are admitted in the UHV chamber through
 102 the main gas inlet shown in Fig. 1. A dedicated mixing chamber is used to prepare the gaseous mixture and to admit it
 103 into the UHV chamber by means of a needle valve, **resulting in a background deposition of ice onto the substrate.**
 104 **This method has the advantage that the film deposited has an uniform thickness, but has the disadvantage that**
 105 **gas phase molecules can freeze out onto all cold surfaces inside the chamber. To prevent any deposition on the**
 106 **backside of the substrate, this is protected by a copper tube aligned with the IR beam and with the central hole**
 107 **of the cold finger (Scirè et al., 2019).** During deposition the thickness of the ice sample is monitored by looking at the

Radiation-induced destruction of organic compounds on the Moon

Figure 1: Schematic view of the experimental set-up.

interference pattern produced by a He-Ne laser beam reflected at near normal incidence by the vacuum-film and film-substrate interfaces. Laser light enters and leaves the chamber through a fused silica window (labeled "multipurpose window" in Fig. 1) whose surface is parallel to the substrate inside the chamber (Urso et al., 2016; Scirè, 2017). **The trend of the interference curve confirms that the deposition rate is constant during accretion and, hence that, the composition of the mixture is homogeneous in the ice sample.** Due to its low vapor pressure, formamide was admitted in the UHV chamber through an inlet mounted on the multipurpose window. In this case, the thickness of the sample is obtained thanks to calibration experiments previously performed (see e.g. Brucato et al., 2006). The UHV chamber is directly connected to a 200 kV ion implanter (Danfysik 1080-200). The ion beam is electrostatically swept to ensure a uniform coverage on the target. In order to avoid a macroscopic heating of the sample, the ion current density is maintained between 100 nA cm^{-2} and a few $\mu\text{A cm}^{-2}$. The ion fluence (ions cm^{-2}) is measured by integrating the ion current monitored during irradiation. After deposition, the ice mixtures are irradiated with 200 keV ions (namely H^+ , He^+ or N^+). The energy deposited by incoming ions to the sample (dose, $\text{eV}/16\text{u}$) is calculated by multiplying the fluence measured during irradiation and the stopping power (eV cm^{-2} per molecule) given by the SRIM software (Ziegler, 1977; Ziegler et al., 1996). The thickness of the samples is kept lower than the penetration depth of impinging ions in order to have a rather uniform energy loss of the ions over the thickness of the ice layer. All the samples are analysed in situ by a Fourier Transform Infrared (FTIR) spectrometer (Bruker, Vertex 70). Spectra with a resolution of 1 cm^{-1} and sampling of 0.25 cm^{-1} are taken. The substrate forms an angle of 45° both with the ion beam and with the infrared beam coming from the IR source of the spectrometer. A hole in the cold finger allows the infrared beam to be transmitted through the infrared transparent substrate so that transmittance IR spectra can be easily taken in situ, even during ion bombardment, without tilting the sample. A rotatable polarizer placed along the path of the IR beam allows to take spectra both with the electric vector parallel (P-polarized) and perpendicular (S-polarized) to the plane of incidence of the infrared beam. In this work, all the shown spectra are acquired in P-polarization because of a better signal-to-noise ratio; indeed, the transmitted signal in P-polarization is higher than the transmitted signal in S-polarization (e.g. Brucato et al., 2006; Urso et al., 2017).

2.1. Ice mixtures

Three $\text{N}_2:\text{CH}_4=1:1$ mixtures are deposited on KBr substrates at 17 K and exposed to 200 keV H^+ , He^+ and N^+ , respectively. Pure formamide and a $\text{Ar}:\text{NH}_2\text{CHO}=25:1$ mixture are accreted onto the cold KBr substrate at 17.5 K. After deposition, NH_2CHO and the $\text{Ar}:\text{NH}_2\text{CHO}$ mixture were irradiated with 200 keV H^+ . In all cases IR transmittance spectra are taken at several intermediate steps of irradiation. **It is known that, among others, ion irradiation causes a removal of surface molecules. This effect, known as sputtering, depends on the mass and energy of impinging ions (e.g. Rothard et al., 2017). While sputtering is negligible after ion irradiation with 200 keV protons (e.g. Loeffler et al., 2005), it is very relevant after irradiation with heavy ions (e.g. Seperuelo Duarte et al., 2010). In order to quantitatively study the destruction of original species induced by ion irradiation it is important to disentangle the effects of sputtering occurring at the surface from the chemical effects occurring in the bulk. With this in mind, prior to irradiation a 300 nm layer of Ar was deposited on each $\text{N}_2:\text{CH}_4$ sample.**

Radiation-induced destruction of organic compounds on the Moon

143 The Ar layer was thick enough to avoid that sputtering affected the $N_2:CH_4$ sample after irradiation with 200
 144 keV He^+ and N^+ ions. The Ar layer was not deposited on the NH_2CHO and $Ar:NH_2CHO$ samples that were
 145 irradiated only with 200 keV H^+ ions.

146 Ice mixtures were selected to constrain the range of destruction cross section values of relevant compounds.
 147 $N_2:CH_4$ mixtures are selected as a template of a sample where we do not expect backward reactions (C+H)
 148 but we have additional destruction pathways which include N. In the case of formamide, we considered two
 149 extreme cases, pure formamide and formamide diluted in Ar, in order to analyze the upper and lower limits of
 150 the destruction cross section range.

151 2.2. Organic refractory residue

152 A $CO:CH_4=1:1$ ice mixture (about 1.2 μm thick) is bombarded by 200 keV H^+ ions at 18 K up to a dose of 120
 153 eV/16u and subsequently warmed up to room temperature to form the organic refractory residue, as shown by Palumbo
 154 et al. (2004) and Accolla et al. (2018). Earlier measurements by Baratta et al. (2015) show that the thickness of the
 155 residue typically decreases by 85–90% compared to the thickness of the un-irradiated ice. Here the thickness of the
 156 residue should be in the range of 0.12–0.18 μm . The residue is then irradiated at 200 K by 200 keV ions; three organic
 157 refractory residues are produced and irradiated with H^+ , He^+ , and N^+ ions, respectively. IR spectra of several organic
 158 refractory residues are shown by Accolla et al. (2018). The absorption bands present in the spectra of the residue
 159 depend on the molecules selected for the initial ice mixtures. If a nitrogen bearing species is present (e.g. N_2)
 160 N-H, and C-N vibrational modes are observed in the spectrum of the residue. Since the N-H stretching mode
 161 partially overlaps with the C-H stretching mode, in the present study we formed the residue starting with a
 162 $CO:CH_4$ ice mixture (i.e. without any N-bearing species). In this case it is possible to obtain the C-H destruction
 163 cross section with higher confidence.

Table 1

Comparison of cross sections. The organic materials are listed from the most volatile to the most refractory.

organic material	temperature (K)	ion type	cross section (16u/eV)
$N_2:CH_4$	17	H^+	0.077 \pm 0.007
		He^+	0.079 \pm 0.006
		N^+	0.077 \pm 0.004
		H^+	0.055 \pm 0.003
		He^+	0.061 \pm 0.002
		N^+	0.063 \pm 0.002
NH_2CHO	17.5	H^+	0.045 \pm 0.004
$Ar:NH_2CHO=25:1$	17.5	H^+	0.886 \pm 0.143
Organic refractory residue	200	H^+	0.002 \pm 0.0003
		He^+	0.008 \pm 0.0006
		N^+	0.024 \pm 0.002

164 In our experimental conditions, the organic refractory residue is stable at room temperature (Baratta et al.,
 165 2019) while $N_2:CH_4$ ice mixtures sublimates at about 30 K (e.g. Collings et al., 2004) and pure formamide at
 166 about 160 K (e.g. Urso et al., 2017). In astrophysical environments, ices are expected to be present in cold regions
 167 while refractory organic material can be present both in cold regions and in warm regions. The temperature of
 168 the surface of the Moon at the equator varies between 400 K (daytime) and 140 K (at night) while at the poles
 169 can be as low as 20 K. In this work organic refractory residues have been irradiated at 200 K considering this
 170 value as an average value for the temperature of organic refractory matter on the lunar surface.

171 2.3. OMERE and SRIM software

172 We used the software Outil de Modélisation de l'Environnement Radiatif Externe (OMERE) to evaluate the
 173 effects of GCRs and SEPs on the Moon. OMERE is a freeware developed by TRAD with support from CNES,
 174 (<https://www.trad.fr/spatial/logiciel-omere/>). OMERE computes the space environment in terms of particle
 175 fluxes and, for a given material, the dose rate ($rad a^{-1}$) as a function of depth. The calculations can be performed
 176 on available orbits or using orbital parameters introduced by the user.
 177 Since OMERE does not account for particles with energy below 10 keV, we estimate the effects of SW ions by

Radiation-induced destruction of organic compounds on the Moon

Figure 2: Evolution of C-H stretching and bending peaks a for $N_2:CH_4$ mixture after ion irradiation: the initial stage is represented in black, and two steps of irradiation in red and blue.

178 means of the software **The Stopping and Range of Ions in Matter (SRIM, <http://www.srim.org/>)**. It is a group
 179 of programs which calculate the stopping and range of ions into matter using a quantum mechanical treatment
 180 of ion-atom collisions (Ziegler, 1977; Ziegler et al., 1996).

181 **The penetration depth of energetic ions depends on its mass and initial energy. For a given ion mass the higher is**
 182 **the initial energy the higher is the penetration depth (that is the depth travelled before stopping). As an example,**
 183 **10 MeV protons would travel in SiO_2 longer than 1 keV protons. SRIM simulations show that H^+ and He^+ ions**
 184 **with energy 1-4 keV do not penetrate deeper than about 0.1 μm , while 10 MeV protons penetrate about 600 μm .**

185 3. Results

186 3.1. $N_2:CH_4$ ice mixtures

187 In Fig. 2 the IR spectra of a $N_2:CH_4$ ice mixture irradiated at 17 K with 200 keV He^+ ions are shown in the spectral
 188 range of methane C-H stretching (3012 cm^{-1}) and bending (1301 cm^{-1}) peaks. The related normalized band area
 189 values as a function of the irradiation dose are reported in Fig. 3. The experimental data are fitted by the exponential
 190 curve

$$191 \quad y = Ae^{-\sigma D} + y_0, \quad (1)$$

192 where D is the dose ($eV/16u$), σ is the cross section ($16u/eV$), y_0 is the asymptotic value and $A + y_0 = 1$. The cross
 193 sections values obtained by the fit are reported in Table 1. The fit results are really good with all the coefficients of
 194 correlation above 0.99. **The good quality of the exponential fit indicates that the destruction of original molecules**
 195 **after ion irradiation is a first order process.** Figure 3 shows that the band area rapidly decreases at the beginning
 196 of irradiation and then reaches a saturation value. We notice that the initial decrease follows the same trend for the
 197 three experiments while the saturation value is about 0.1 in the case of irradiation with 200 keV H^+ and He^+ ions, and
 198 it is about 0.2 in the case of irradiation with 200 keV N^+ ions. We speculate that this difference is due to the lower
 199 penetration depth of N^+ ions in the target ice, as estimated by means of SRIM software (Ziegler et al., 1996). **In fact**
 200 **in the passage through a solid target energetic ions lose energy both to electronic excitations and to momentum**
 201 **transfer to target nuclei (e.g. Johnson, 1990; Rothard et al., 2017). As a consequence the energy loss per unit**
 202 **path length, often referred to as stopping power, determines the penetration depth of impinging ions. In turns,**
 203 **at a given energy, ions with higher stopping power values travel a shorter distance in matter. As given by SRIM**
 204 **software (Ziegler et al., 1996) the stopping power of N^+ ions in a $N_2:CH_4$ ice sample is about 26 $eV/\text{\AA}$ that is**
 205 **higher than the stopping power of H^+ and He^+ ions, about 6.5 $eV/\text{\AA}$ and 16 $eV/\text{\AA}$ respectively.** Similar values of
 206 cross sections, under the irradiation with the three different ions, are found. It can be concluded that the destruction
 cross section of C-H bonds in $N_2:CH_4$ ice mixture does not depend on the ions that irradiate the material.

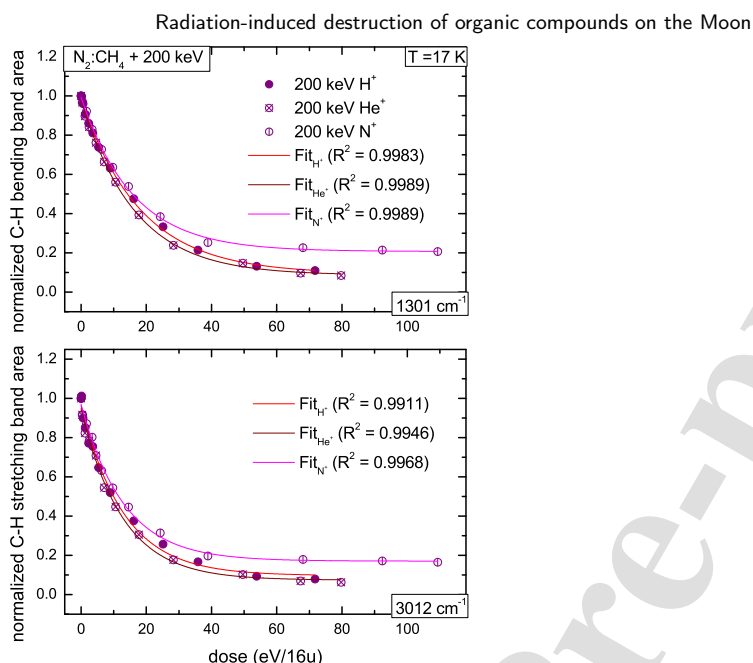

Figure 3: Normalized C-H bending and C-H stretching band area of N₂:CH₄ mixtures after ion bombardment plotted vs. irradiation dose. The graphs show data resulting from the irradiation with H⁺, He⁺ and N⁺ 200 keV ions and the fit obtained using Eq. 1.

3.2. Pure and diluted NH₂CHO

In Fig. 4 the IR spectra of pure NH₂CHO and a Ar:NH₂CHO=25:1 mixture are shown; following Brucato et al. (2006) and Urso et al. (2017), the main vibrational features are labelled. The profile of the infrared bands shows significant differences: in general, formamide diluted in an Ar matrix has narrower bands. A similar result is obtained for a CO:NH₂CHO mixture (e.g. Urso et al., 2017). In Fig. 5 there is a detail of the spectra in the C-H bending (1388 cm⁻¹) and C-N stretching (1328 cm⁻¹) peak regions: the initial (black line) and two steps (red and blue lines) of irradiation are reported. In Fig. 6 the values of the normalized band area for the two ice samples are plotted. In the case of pure formamide, we considered the area of the double peak feature due to the superposition of the C-H bending and C-N stretching modes; instead, for Ar:NH₂CHO mixture, the area of the C-H bending mode band was evaluated. Experimental data are fitted with an exponential equation (Eq. 1). The fit gives the cross section values (σ) reported in Table 1. The normalized band area is the area of the band at each step of irradiation divided by the initial value before irradiation. We notice that after the first step of irradiation the area of the band increases and the normalized value is greater than 1. This effect has been observed also after ion irradiation of other ice samples (e.g. Loeffler et al., 2005; Garozzo et al., 2011) and is ascribed to a modification of the structure of the sample which in turn causes a variation of the band strength value.

3.3. Organic refractory residue

In Fig. 7, the IR spectra of an organic refractory residue in the 3150-2650 cm⁻¹ region are shown; the three peaks close to each other (2960, 2927 and 2870 cm⁻¹) are characteristic of the aliphatic -CH₂ and -CH₃ bonds. Three samples have been irradiated with 200 keV H⁺, He⁺, and N⁺, respectively. For each sample the normalized band area is plotted as a function of the irradiation dose in Fig. 8. Experimental data points are fitted by an exponential curve (Eq. 1). The destruction cross section values obtained by the fit are reported in Table 1. All the fittings are very good, with coefficients of correlation R² around 0.99.; the choice of the decreasing exponential fitting is then accurate. It was found that the value of cross section depends on the irradiating ion. Indeed, for 200 keV N⁺ a cross section ten times higher than for 200 keV H⁺ and three times higher for 200 keV He⁺ was found.

Radiation-induced destruction of organic compounds on the Moon

Figure 4: Infrared spectra in optical depth scale of pure and diluted formamide (17.5 K) samples acquired before irradiation with 200 keV H^+ ions.

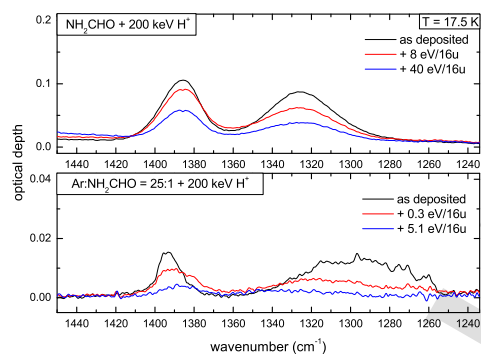

Figure 5: Evolution of C-H and C-N peaks for pure and diluted formamide ice samples: the initial stage is represented in black, and two steps of irradiation in red and blue.

3.4. Estimation of the radiation dose on the Moon

3.4.1. Solar Energetic Particles and Galactic Cosmic Rays

After the experiments, the OMERE software was utilized to evaluate the effects of GCRs and SEPs on the Moon. A lunar orbit simulation was used to make the assessment. Figure 9 shows the dose rate as a function of depth calculated by OMERE. The dose is given in units of rad, where $1 \text{ rad} = 10^{-2} \text{ Gy} = 1.7 \times 10^{-9} \text{ eV/16u}$ (Baratta et al., 2019). The radiation environment on the Moon has been the subject of several investigations. Both simulations and real measurements in situ have been performed (e.g. de Angelis et al., 2008; Schwadron et al., 2012; Crites et al., 2013). In particular, Schwadron et al. (2012) report the dose rate measured at the surface of the Moon by the CRaTER instrument on board the Lunar Reconnaissance Orbiter (LRO) mission as well as dose rate values obtained by ACE (Advanced Composition Explorer) spacecraft. The values obtained by OMERE software, shown in Fig. 9, are comparable to the values reported by Schwadron et al. (2012) that are in the range of 5-10 Gy/a at the Moon surface. Using the destruction cross section values reported in Table 1 and the dose rate given by OMERE, we have evaluated the lifetime of organic species on the Moon as a function of depth, i.e. the time required for the concentration of a chemical species to decrease to $1/e$ of its original value. Results are reported in Fig. 10.

3.4.2. Solar wind

In addition to GCRs and SEPs, solar system objects are also exposed to SW, a supersonic flux of ions and electrons released from the solar corona. The ion flux is on the order of $2 \times 10^8 \text{ ions cm}^{-2} \text{ s}^{-1}$ (Schwenn, 2001) at 1 au (astronomical unit, $1.495 \times 10^{11} \text{ m}$), with an energy of 1 keV per atomic mass unit. The SW ions consist of H^+

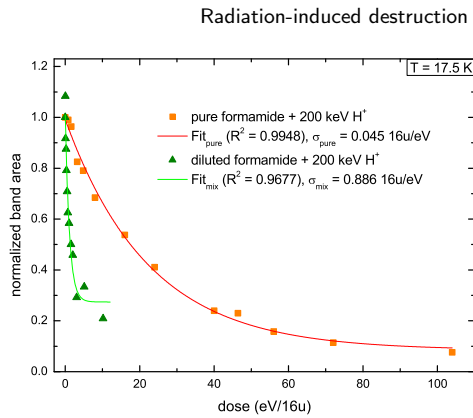

Figure 6: Normalized band area of pure and diluted formamide after ion bombardment plotted vs. irradiation dose. The graph shows data resulting from the irradiation with H^+ 200 keV ions and the fit obtained using Eq. 1.

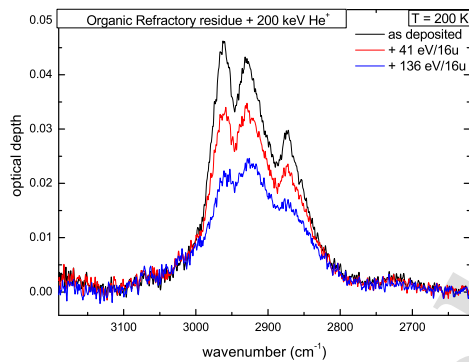

Figure 7: Evolution of C-H stretching mode feature for the organic refractory residue: the initial stage is represented in black, and two steps of irradiation in red and blue.

249 (96%) and He^{2+} (4%), heavier elements having abundances $<0.1\%$. The flux decays as $1/r^2$, where r is the distance
 250 from the Sun (e.g. Baratta et al., 2004). Since OMERE does not account for particles with energy below 10 keV, we
 251 estimate the effects of SW ions by means of SRIM. Table 2 displays SRIM input parameters and outcomes. Calculation
 252 were made considering a layer of SiO_2 (thickness = 1000 Å). The different abundance of hydrogen and helium ions
 253 was also taken into account. We considered three cross section values among those reported in Table 1, i.e. the smallest
 254 ($\sigma_1 = 0.002$ 16u/eV), an intermediate one ($\sigma_2 = 0.045$ 16u/eV) and the highest ($\sigma_3 = 0.886$ 16u/eV) to estimate the
 255 lifetime of organic species; the results show that SW ions affect the uppermost 100 nm surface layers and that the
 256 lifetime ranges between a fraction of year and 10^3 a.

257 3.5. Estimation of impact gardening effects

258 Impact gardening is known to affect the surface of airless solar system bodies (e.g. Costello et al., 2020, 2021): this
 259 phenomenon stir and mix the outermost crust provoking resurfacing. As a consequence, impact gardening and space
 260 weathering processes compete with each other. As shown by Costello et al. (2021), impact gardening is a fast process
 261 at the surface while it is slower as depth increases. Taking into account the rate at which gardening proceeds to greater
 262 depth with time reported by Costello et al. (2021), we estimated the fraction of surviving organic matter for the Moon
 263 as a function of depth over its age.

264 Given the dose rate $d(x)$ shown in Fig.9 and the gardening time $t_G(x)$ reported in Costello et al. (2021), the
 265 dose $D(x)$ in eV/16u, is given by

Radiation-induced destruction of organic compounds on the Moon

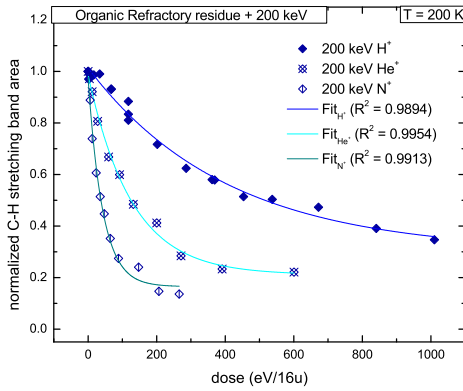

Figure 8: Normalized C-H stretching band area of the organic refractory residue after ion bombardment plotted vs. irradiation dose. The graph shows data obtained from the irradiation with 200 keV H⁺, He⁺ and N⁺ and the fit obtained using Eq. 1.

Figure 9: Dose rate vs. depth as calculated by OMERE software (<https://www.trad.fr/spatial/logiciel-omere/>).

Table 2

SRIM calculation parameters and results. The input layer thickness is 1000 Å for each measurement. The lifetime under SW irradiation has been estimated using the cross sections σ_1 , σ_2 and σ_3 , which refer respectively to the organic residue, NH₂CHO and Ar:NH₂CHO mixture.

layer composition	density (g cm ⁻³)	ion (energy)	stopping power (eV/Å)	dose rate (10 ⁻⁶ eV/16u s)	penetration depth (Å)	lifetime (a*)		
						σ_1	σ_2	σ_3
SiO ₂	2.7	H ⁺ (1 keV)	2.5	0.48	292	67	3.5	0.2
SiO ₂	2.7	He ²⁺ (4 keV)	4	0.03	573	1000	50	2.3

*a is the IUPAC symbol for year

$$D(x) = 1.7 \times 10^{-9} \times d(x) \times t_G(x). \quad (2)$$

266

Then the fraction of surviving organic matter is obtained by

Radiation-induced destruction of organic compounds on the Moon

Figure 10: Lifetime on the Moon surface of analyzed organic materials resulting from OMERE simulation of SEPs and GCRs effects vs. depth.

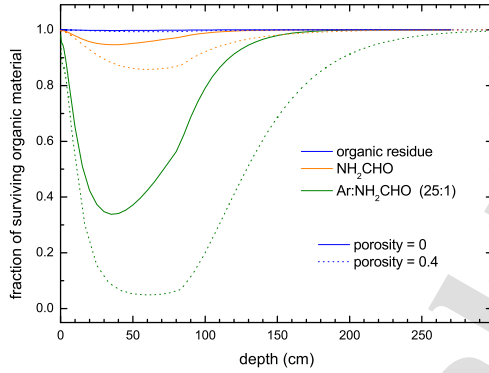

Figure 11: Estimated fraction of surviving organic matter on the Moon as a function of depth. Three different values of destruction cross section and two different values of lunar regolith porosity were used.

$$y(x) = \frac{N(x)}{N_0} = e^{-\sigma D(x)}, \quad (3)$$

where σ (16u/eV) is the cross section obtained experimentally.

In Fig. 11 the results for three different values of destruction cross section (namely $\sigma_1 = 0.002$ 16u/eV, $\sigma_2 = 0.045$ 16u/eV, and $\sigma_3 = 0.886$ 16u/eV) and for two different values of lunar regolith porosity are reported. As shown by Costello et al. (2021), impact gardening is a fast process at the surface while it is slower as depth increases. This means that at the surface the material is irradiated (space weathering) for a short time and a significant fraction of organic matter, if present, would survive. As we move inward, the gardening process is slower and the material is irradiated for longer time; this means that the fraction of organic matter that survives is smaller. As depth increases further the gardening process is even slower and in principle organic matter could be irradiated for longer time however at greater depth the dose rate decreases significantly (see Fig. 9) and as a consequence the fraction of present organic matter that survive is high. Porosity is a measure of voids in the regolith matter. The dose rate values reported in Fig. 9 refer to a compact solid. If voids were present, the dose rate at a given depth would be higher. In turns this means that at a given depth space weathering effects would be higher and the surviving fraction of organic material would be smaller.

4. Discussion

We obtained the destruction cross section under ion irradiation of compounds that simulate organics at the Moon's surface. Our work extends previous investigations on the survival of organic substances irradiated by fast ions (e.g. Gerakines et al., 2012; Gerakines and Hudson, 2013; Urso et al., 2022) and UV photons (e.g. Fornaro et al., 2018; Baratta et al., 2019; Corazzi et al., 2020; Suhasaria and Mennella, 2022). We found that (1) for a given species (e.g. NH_2CHO) the destruction cross section depends on the matrix it is embedded in with; in fact, if NH_2CHO is highly diluted in an inert matrix, the destruction cross section is more than one order of magnitude higher than the value obtained in the case of pure NH_2CHO ; **This result has already been reported in the case of ion irradiation of pure H_2O ice and H_2O -rich ice mixtures (e.g. Gomis et al., 2004; Garozzo et al., 2011) and H_2O trapped in a matrix (Fulvio et al., 2010). In fact when energetic ions travel through the target the energy they release causes the break of chemical bonds which in turn causes the formation of radicals and fragments. These radicals and fragments might react to each other and form molecular species not originally present in the target. In the case of a target made of a single molecular species the probability of chemical reactions which re-form the original species (backward reactions) is very high. When a given molecular species is highly diluted in a matrix the probability of backward reactions is very low and the species is rapidly destroyed.** (2) in the case of the organic refractory residue, the destruction cross section is more than one order of magnitude lower than the value obtained for volatile species. Furthermore, we used different ions at 200 keV energy (namely H^+ , He^+ , and N^+) and we found that the destruction cross section value for an ice mixture is independent of the projectile (see Table 1). This result is in agreement with the recent work by De Sanctis et al. (2023): they found the same value of destruction cross section after ion irradiation of an aliphatic organic compound (undecanoic acid, $\text{C}_{10}\text{H}_{21}\text{COOH}$) mixed with minerals. The organic refractory residue is a carbon-rich material with several functional groups embedded in a complex structure (e.g. Palumbo et al., 2004; Accolla et al., 2018; Urso et al., 2020). The destruction cross section value of residues exposed to ion bombardment varies by nearly an order of magnitude when different projectiles are taken into account (see Table 1). **This is the first time that such a result is reported for organic refractory residues. The comprehension of the physico-chemical mechanisms which give this result is beyond the scope of this work. We are planning further experiments to shed light on the processes at the origin of the differences we observed. Furthermore, we plan to perform new experiments considering different organic refractory residues and other refractory organic compounds to verify the generality of this result.**

Energetic charged particles of all energies can strike the lunar surface since there is neither a magnetic shield nor an atmosphere. We estimated the dose rate due to GCRs and SEPs at the Moon (see Fig. 9) and, with the cross section values measured experimentally, we obtained the expected lifetime of organic compounds on the surface of the Moon (see Fig. 10). As shown in Figs. 9 and 10, SEPs and GCRs effects prevail over each other based on depth; in the uppermost layers the action of SEPs is dominant, while below about 2 cm from the surface, the dose rate and hence the lifetime of organic compounds depend on GCRs. Moreover, running SRIM software we estimated the lifetime considering the contribution by SW ions that is relevant in the topmost 100 nm of the surface (see Table 2).

In Fig. 11 we plot the fraction of surviving organic material assuming the impact gardening model by Costello et al. (2021) and the dose rate and destruction cross section presented in this work. The trend shown in Fig. 11 describes the expected fraction of surviving organic materials in those regions exposed to energetic radiation (**i.e. both SEPs and GCRs effects are present**).

The description of the fate of organic species in permanently shadowed regions (PSRs) at the lunar poles is not straightforward. In fact, in those regions the evolution of volatile species is driven also by diffusion and sublimation. These regions are characterized by low surface temperatures ($T < 100$ K), which allow the presence of water ice (e.g. Watson et al., 1961; Gläser et al., 2021). Other volatile species are expected to be trapped in it and, indeed, have been detected in the LCROSS ejecta plume (Colaprete et al., 2010) and by the observations obtained with the Nighttime Lyman Alpha Mapping Project (LAMP) UV spectrograph onboard the LRO (Magaña et al., 2023). However, the presence of super volatile species (such as CH_4 , N_2 , and CO) requires temperature values as low as 20-30 K (e.g. O'Brien and Byrne, 2022, and references therein). Laboratory experiments have shown that, at temperatures lower than the sublimation temperature, volatiles species such as CH_4 , N_2 , and CO diffuse in water ice (Palumbo, 2006; Raut et al., 2007; Fulvio et al., 2010). It is expected that molecules that diffuse toward the surface would rapidly sublimate while molecules that diffuse inward would remain trapped in cold icy layers. This is consistent with the detection of CH_4 in the LCROSS ejecta plume originating from layers deeper than about 0.7 m (Colaprete et al., 2010). Less volatile species, such as NH_2CHO , and the organic refractory residue are not expected to be affected by diffusion and

Radiation-induced destruction of organic compounds on the Moon

332 sublimation. **In permanently shadowed regions the flux of energetic ions is expected to be lower than the flux**
 333 **on regions fully exposed to solar radiation. As a consequence also the dose rate is expected to be lower while**
 334 **the impact gardening is not expected to vary significantly with solar irradiation. Then the fraction of surviving**
 335 **material reported in Fig. 11 would be underestimated because it has been obtained considering both SEPs and**
 336 **GCRs effects.** As a consequence, the values of the surviving fraction reported in Fig. 11 can be regarded as a lower
 337 limit. Finally, the fraction of surviving organic refractory residue is close to 1 even in regions exposed to solar radiation.

338 C-rich materials were detected on the surface of black pyroclastic beads collected in the Shorty crater during the
 339 Apollo 17 mission. Thomas-Keprta et al. (2014) explained their presence considering the delivery of exogenous C-rich
 340 matter from micrometeorite impacts. This C-rich material is on average more disordered than the C-rich material in
 341 IDPs collected on Earth. Our experiments show that the exposure of organic residues to 200 keV ions causes the
 342 destruction of the C-H bonds with increasing the dose. Previous experiments (Strazzulla and Baratta, 1992; Ferini
 343 et al., 2004; Palumbo et al., 2004; Urso et al., 2020) showed that increasing irradiation dose causes the loss of the
 344 H content of organic materials and their progressive conversion into amorphous carbon. Such material presents a
 345 featureless IR spectrum but shows characteristic bands in Raman spectra (G and D lines at 1560 and 1360 cm^{-1} ,
 346 respectively). **As discussed above, organic refractory residues obtained after ion irradiation of simple ices can**
 347 **be considered analogues of organic matter in space. Indeed they are good spectral analogues of extraterrestrial**
 348 **organic material detected in micrometeorites and interplanetary dust particles (IDPs) (Baratta et al., 2015;**
 349 **Potapov et al., 2022).**

350 **These results are compatible with the hypothesis that refractory carbonaceous matter detected on the Moon has**
 351 **an exogenous origin and its high disorder level is a consequence of the exposure to energetic radiation.**

352 5. Acknowledgments

Highlights

- Formamide, methane, and a refractory organic residue as lunar organic matter analogue
- Measurements of radiation-induced destruction cross section of organic compounds
- Estimation of organic compounds lifetime on the Moon
- Effects of solar wind, energetic particles, and gardening on lunar organic compounds

Declaration of interests

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.
