18 **Abstract.** Understanding optical and radiative properties of aerosols and clouds is critical to reduce uncertainties
19 in climate models. For over 10 years, the Observatory of Atmospheric Physics of La Réunion (OPAR) has been
20 operating three active lidar instruments (named Li1200, LiO3S and LiO3T) providing time-series of vertical
21 profiles from 3 to 45 km of the aerosol extinction and backscatter coefficients at 355 and 532 nm, as well as the
22 linear depolarization ratio at 532 nm. This work provides a full technical description of the three systems, details
23 about the methods chosen for the signal preprocessing and processing, and an uncertainty analysis. About 1737
24 night-time averaged profiles were manually screened to provide cloud-free and artifact-free profiles. Data
25 processing consisted in Klett inversion to retrieve aerosol optical products from preprocessed files. The
26 measurement frequency was lower during the wet season and the holiday periods. There is a good correlation
27 between the Li1200 and LiO3S in terms of stratospheric AOD at 355 nm ($0.001-0.107$; $R = 0.92 \pm 0.01$), and with
28 the LiO3T in terms of Angström exponent 355/532 ($0.079-1.288$; $R = 0.90 \pm 0.13$). The lowest values of the
29 averaged uncertainty of the aerosol backscatter coefficient for the three time-series are 64.4 ± 31.6 % for the
30 LiO3S, 50.3 ± 29.0 % for the Li1200, and 69.1 ± 42.7 % for the LiO3T. These relative uncertainties are high for
31 the three instruments because of the very low values of extinction and backscatter coefficients for background
32 aerosols above Maïdo observatory. Uncertainty increases due to SNR decrease above 25 km for the LIO3S and
33 Li1200, and 20 km for the LiO3T. The LR is responsible for an uncertainty increase below 18 km (10 km) for the
34 LiO3S and Li1200 (LiO3T). The LiO3S is the most stable instrument at 355 nm due to less technical modifications
35 and less misalignments. The Li1200 is a valuable addition to fill in the gaps in the LiO3S time-series at 355 nm or
36 for specific case-studies about the middle and low troposphere. Data described in this work are available at
37 <https://doi.org/10.26171/rwcm-q370> (Gantois et al., 2024).

38 **1. Introduction**

39 Uncertainties concerning aerosol and cloud optical and radiative properties strongly affect surface climate and
40 also the accuracy in climate models (Hansen et al., 1997; Alexander et al., 2013). Aerosols can be of multiple

41 origins, compositions, sizes, and shapes, but can also interact at different temporal and spatial scales and be
42 influenced by various dynamical processes. This makes their observation at the global scale and the modelling of
43 their properties challenging. Improving our knowledge in this area implies to use different measurement techniques
44 (in situ, active and passive remote sensing methods) synergistically and to provide continuous timeseries of high-
45 resolution measurements in the low and middle atmosphere.

46 The Observatory of Atmospheric Physics of La Réunion (OPAR), located on Réunion Island near Madagascar,
47 is currently equipped with more than 50 instruments distributed over three different sites: two historical coastal
48 sites in the north, and a high-altitude site (Maïdo observatory, 2160 m asl, Baray et al., 2013), which now houses
49 more than two-thirds of these instruments. OPAR is part of many international networks, including GAW (Global
50 Atmospheric Watch), NDACC (Network for the Detection of Atmospheric Composition Change), SHADOZ
51 (Southern Hemisphere Additional OZonesondes), and AERONET (Aerosol Robotic Network). Additionally, it is
52 a part of the European research infrastructures ACTRIS (Aerosol, Clouds, and Trace Gases Research
53 Infrastructure) and ICOS (Integrated Carbon Observing System).

54 Maïdo observatory (21.079°S, 55.383°E) is one of the very few active observational sites in the Southern
55 Hemisphere (SH). It is scarcely influenced by anthropic aerosols. Its importance lies in the fact that the aerosol
56 load in the atmosphere above Reunion Island is under the influence of many different sources of emission and
57 dynamical processes responsible for short and long-range air-mass transports (Baray et al., 2013) such as biomass
58 burning (BB) plumes (Edwards et al., 2006; Khaykin et al., 2020), which are emitted seasonally in the SH.
59 Moreover, it is not rare for volcanic aerosols to be detected in the stratosphere above Maïdo observatory. In fact,
60 several volcanoes are located at the same latitude (Hunga-Tonga), or in the same Hemisphere (Calbuco) as Reunion
61 Island (Bègue et al., 2017; Khaykin et al., 2017; Tidiga et al., 2022; Baron et al., 2023; Sicard et al., 2023). The
62 high altitude of this facility is also of great importance as it is located above the boundary layer during the night,
63 allowing the observation of the free troposphere in a quasi-pristine environment.

64 Since its creation in 2012, the Maïdo facility has been equipped with four research lidar (light detection and
65 ranging) instruments emitting electromagnetic radiations at different wavelengths. Three of them have been
66 providing high resolution time series of aerosol extinction and backscatter vertical profiles in the UV (355 nm)
67 and visible (532 nm) domains. As of today, these measurements have only been used occasionally for case studies
68 (Bègue et al., 2017; Khaykin et al., 2017; Tidiga et al., 2022; Baron et al., 2023; Sicard et al., 2023). Full
69 exploitation of these timeseries will enable to provide timeseries of aerosol extinction and backscatter profiles over
70 Reunion Island. This can only be achieved after homogenizing the processing method for the three instruments.

71 This work provides a summary of the specifications of the systems and a full description of the preprocessing
72 and processing methods used to produce different levels of the datasets for the three Maïdo lidars.

73 2. Instrumental description

74 **Table 1** is a summary of the characteristics of the three Maïdo lidars used to retrieve aerosol optical properties. A
75 full description of each system is available in the following subsections.

79

80 2.1. Lidar 1200 (Li1200)

81 The Li1200 is a Rayleigh Raman lidar able to measure vertical profiles of temperature between 30 and 100 km asl
 82 and water vapor ratio from the ground up to 18 km (Vérèmes et al., 2019). Vertical profiles of aerosol light
 83 extinction and backscattering can also be retrieved from the raw signals, as this instrument provides Rayleigh-Mie
 84 scattering at 355 nm and Raman N₂ scattering at 387 nm. This instrument has been operating at the Maïdo facility
 85 since 2012 and produces data since 2013.

86 (i) Actual configuration

87 **The emission** consists in two Nd: YAG Quanta Ray pro 290 lasers, from Spectra-Physics, emitting
 88 electromagnetic pulses at 1064 nm and 30 Hz. The final wavelength emitted is 355 nm, which corresponds to the
 89 third harmonic of the initial wavelength. Each pulse delivers 375 mJ in 9 ns. The optical design of this lidar is
 90 represented in **Figure 1**. The two laser beams are recombined through a polarizer cube, then sent to the telescope
 91 through a series of mirrors. It should be noted that the lasers and the telescope are not in the same room, hence the
 92 use of many mirrors. BE1 and BE2 lenses form an afocal of magnification 1.25, reducing the divergence of the

93 beams and mixing the phases. The goal is to reduce the hot spots, especially on the very fragile optic BE3. Last,
94 the laser beam is channeled through the center of the main telescope and magnified by a factor of 10 thanks to the
95 afocal system BE3 and BE4. The emission and main reception are therefore static coaxial, reducing the parallax
96 effect and the minimum overlap altitude.

97 **The reception** is made of two telescopes. The main telescope consists in a primary mirror of 1200 mm diameter
98 (M1200), which gave its name to this instrument. A secondary mirror HM sends the beam to the detection system.
99 The L1 lens allows the beam to converge faster, which explains the 3.6 m value of the focal length. GS1 is a glass
100 plate that sends about 8 % of the beam on the 355 nm Very Low (355VL channel) detector. As this detector is
101 located before the FD2 diaphragm, its field of view is the same as the one of the telescope, and it receives signal
102 in the very near-range. A density (ND) was placed in front of this detector to avoid saturation. FD2 is a diaphragm,
103 located at the focal plane of the telescope. Its aperture improves the geometrical factor of the telescope for the
104 detectors following it. DM1 is a dichroic filter that reflects 355nm and allows 387nm and 407nm to pass through.
105 GS2 is a glass plate that sends about 8% of the beam on the 355 nm Medium (355M) channel and 92% of the beam
106 on the 355nm High (355H) channel. DM3 is a dichroic filter which selects the 387 nm for the Raman N2 channel.
107 As of 2017, a second telescope, with a 200 mm M200 primary mirror and a focal length of 1 m, sends the signal
108 to a second detection box, using an optical fiber. This detection box filters the Rayleigh and Raman signals and
109 channels them respectively to the 355L and 387L detectors.

110 All the **detectors** are photomultiplier tubes (PMT) from Hamamatsu, reconditioned by the Licel company
111 (<http://licel.com>). The 355H, 355M, and 355L detectors are electronically shuttered to prevent saturation. The
112 **acquisition** cards also come from Licel and operate in photocounting mode. There are no analog channels. Raw
113 files follow a 1-minute integration.

114 **To summarize**, 355M and 355H channels exist since 2013, but their acquisition starts at 15 and 25 km,
115 respectively, to avoid saturation. Hence, the 355VL and 355L channels were added in 2017 to cover the first
116 altitude ranges below 15 km. The minimum height for 355L electronic shuttering is 450 m asl.

117 *(ii) Previous modifications*

118 The detection unit was modified in 2017. Before that, the detection unit containing the 355L and 387VL
119 detectors did not exist. The M1200 mirror separation unit was modified. First, the part containing the FD1 to L3
120 optics, as well as the 355VL detector, did not exist. And there was an optic between IF2 and DM2 that would send
121 the visible signal to another detection unit. Indeed, originally, this lidar was supposed to operate at two emission
122 wavelengths, 355 and 532nm. However, during installation, due to mechanical and optical problems, only the 355
123 nm channel was retained (Dionisi et al., 2015).

Figure 1 : Li1200 optical scheme

2.2. Stratospheric Ozone Lidar (LiO3S)

The Stratospheric Ozone Lidar (LiO3S) works with the Differential Absorption Lidar (DIAL) technique and provides vertical profiles of ozone (O_3) concentration in the stratosphere, between the tropopause and about 45 km (Godin-Beekmann et al., 2003; Portafaix et al., 2003). To this end, two different wavelengths are emitted: a 308 nm signal strongly absorbed by ozone molecules and a 355 nm signal weakly absorbed by ozone molecules. Vertical profiles of aerosol light extinction and backscattering can be retrieved from the elastic scattering at 355 nm and Raman N_2 scattering at 387 nm. From 2000 to 2012, the LiO3S was located at the Moufia University campsite in Saint-Denis and provided ozone vertical profiles. It was moved to the Maïdo facility in 2012 and has been measuring from this location since 2013.

(i) Actual configuration

The emission set-up consists in two different lasers. A XeCl PulseMaster PM-800 Series excimer laser, from LightMachinery, emits electromagnetic pulses at 308 nm wavelength with a frequency of 40 Hz and pulse energy of 220 mJ. A Nd:YAG Lab 150 laser from Spectra-Physics emits electromagnetic pulse at a 1064 nm wavelength with a frequency of 30 Hz. The final wavelength emitted by the Nd:YAG laser is 355 nm, corresponding to the third harmonic of the emitted wavelength. The pulse energy at this wavelength is 130 mJ. The laser beam diameter is about 10 mm, and its divergence is 0.5 mrad. The optical design of this lidar is represented in Figure 2. Again, the emission and reception of this lidar are located in different rooms, explaining the use of many mirrors. The expander consists in three lenses, BE1, BE2 and BE3, magnifying the signal by a factor 10. The final beam has a 100 mm diameter.

145 **The reception** is made of four 500 mm diameter telescopes. The primary mirrors are M1, M2, M3 and M4.
 146 The signal is emitted at the center of these telescopes, and the distance between the emission and the center of each
 147 telescope is 600 mm. At the receiving end, the signal is a focused from each telescope to a corresponding optical
 148 fiber, which are positioned in line before entering the detection box. In this box, a diffraction grating separates the
 149 different wavelengths. Internal mirrors allow the beam to be reflected in the detectors. Finally, a glass plate
 150 discriminates the high and low energy channels at 355 nm.

151 All the **detectors** are PMT from Hamamatsu and the signal **acquisition** cards are from Licel. The 355 nm
 152 detectors are electronically shuttered to avoid saturation. The acquisition is in photocounting mode only for the
 153 high energy channels, and in photocounting and analog mode for the low energy channels. Raw files follow a
 154 1minute integration.

155 (ii) *Previous modifications*

156 Before 2017, the electronic obturation concerned only 355H and 308H channels, and a mechanical chopper
 157 shuttered 355M, 308M and Raman channels at the entrance of the detection box. In 2017, this chopper
 158 malfunctioned and was replaced by electronic obturation for the 355M and 308M channel. Raman channels were
 159 not shuttered anymore. The initial integration time was 3 minutes and was reduced to 2 and then 1 minute. During
 160 this period, the vertical resolution was modified from 120 m to 15 m.

161

Figure 2 : LiO3S optical scheme

162

163 2.3. Tropospheric Ozone Lidar (LiO3T)

164 The Tropospheric Ozone Lidar (LiO3T) also works with the DIAL technique and provides vertical profiles of
165 ozone (O_3) concentration in the troposphere, between 6 and 25 km (Duflot et al., 2017). To this end, two different
166 wavelengths are emitted using stimulated Raman scattering: a 289 nm signal strongly absorbed by ozone molecules
167 and a 316 nm signal weakly absorbed by ozone molecules. Vertical profiles of aerosol light extinction and
168 backscattering can be retrieved from the residual emission of the laser in terms of elastic scattering at 532 nm and
169 1064 nm, and Raman N_2 scattering at 607 nm. From 1993 to 2012, the LiO3T was located at the Moufia University
170 campsite in Saint-Denis and provided ozone vertical profiles. It was moved to the Maïdo facility in 2012 and has
171 been measuring from this location since 2013. The first aerosol dedicated polarized channels were installed in
172 2014.

173 (i) *Actual configuration*

174 **The emission** consists in a Quanta Ray Pro 290 laser from Spectra-Physics emitting initially at 1064 nm at 30
175 Hz. While the fourth harmonic (266 nm) is used to retrieve tropospheric ozone profiles (through its passage in a
176 Raman cell generating 289 and 316 nm pulses), we use the second harmonic (532 nm) to retrieve aerosol light
177 extinction and backscattering. Each pulse at 532 nm provides an energy of 250 mJ. The laser beam diameter is of
178 about 10 mm, and its divergence is about 0.5 mrad. The optical design of this lidar for aerosol measurements is
179 represented in **Figure 3**. Again, the emission and reception of this lidar are located in different rooms, explaining
180 the use of many mirrors. The lenses, BE1, BE2 and BE3, magnify the signal by a 15 factor. The final emitted beam
181 diameter is 100 mm.

182 **The reception** is made of two telescopes: one for the Rayleigh and Raman channels (532, 607 and 1064 nm,
183 respectively), and the other for the polarized channels at 532 nm. The first telescope (M500) consists in a 500 mm
184 diameter primary mirror. An optical fiber located at its focal point, conducts the signal to the detection box.
185 Dichroic filters separate the 532, 607 and 1064 nm wavelengths. The second telescope consists in a 200 mm
186 diameter primary mirror immediately followed by a polarizing cube. An optical fiber leads the polarized and cross-
187 polarized beams to interference filters and to the detectors.

188 All the **detectors** are PMT from Hamamatsu, except for the 1064 nm detector, which is an avalanche diode
189 with a 3 mm diameter sensor. The 532 high energy channel (532H) detector is the only one electronically shuttered.
190 All the **acquisition** cards are from Licel. The acquisition of the 532 nm polarized channel as well as the 607 nm
191 channel are in photocounting mode. The acquisition of the 532H channel is in photocounting and analog modes,
192 and the acquisition of the 1064nm channel is only in analog mode. Raw files follow a 2-minute integration.

193 (ii) *Previous modifications*

194 In 2014, the 200 mm telescope (M200) and the T200 wavelength separation unit were installed, allowing for the
195 first aerosol measurements with polarized channels. In 2017, one of the four 500 mm telescopes initially dedicated
196 to ozone measurements was used for aerosol measurements. A second detection box was added, enabling the 607
197 nm and 1064 nm channels acquisition.

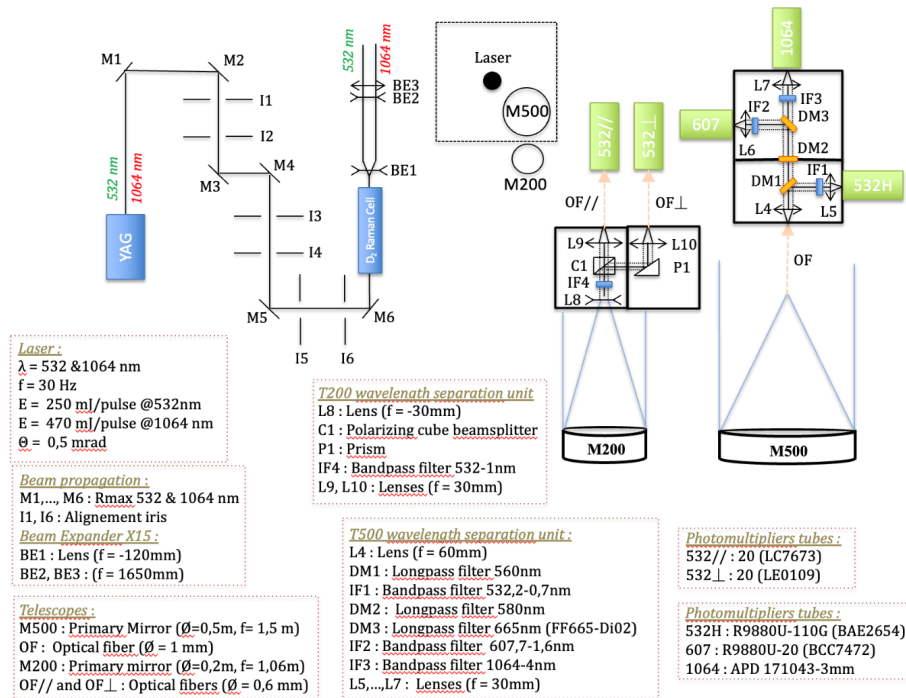

Figure 3 : LiO3T optical scheme

198

199

200 3. Routine measurements

201 The Maïdo lidars are research instruments that require manual handling and a constant human presence while
 202 operating. Maïdo observatory is a high-altitude facility (2160 m asl) and is located above the boundary layer in the
 203 free troposphere during the night. Acquisitions are only made during the night to increase the SNR. These
 204 instruments were originally intended to observe data in the stratosphere and the upper troposphere, so they are
 205 optimized to work at night, to improve the SNR up to very high in the atmosphere. That is why acquisitions are
 206 only made during the night. Measurements also require the absence of low-clouds or rain. The position of the
 207 Maïdo observatory on the west side of Reunion Island often protects the site from the clouds brought by trade
 208 winds. Notably, a ceilometer was installed at the Maïdo facility in 2019 and continuous observations revealed an
 209 average cloud frequency of respectively 20% and 40% during winter and summer nights (not shown).

210 Routinely, Maïdo lidars are operated two nights per week and measurements last from 7pm to 1am (local time,
 211 i.e. from 15 to 21 UTC). Specific campaigns (once or twice a year) can occasionally require to significantly
 212 increase the number of measurements. Operating these instruments implies to follow a strict, well-prepared
 213 protocol including basic check-ups and laser power control. A metadata file is routinely fed with technical specifics
 214 for each night of observation and after any instrumental modification. Automatization is currently in progress and
 215 could increase the frequency of routine measurements.

216 4. Data processing chain

217

218

4.1. Data processing levels

219 Our datasets follow a classification detailed in the following description. Data processing levels range from Level
220 0 to Level 2.

- 221 (i) Level 0 products (L_0) are uncorrected and uncalibrated raw data files in Licel format at full
222 resolution produced by the instrument.
- 223 (ii) Level 1 products (L_1) provide cloud-free data cleaned from any instrumental artifact (electronic
224 parasites, synchronization problems, power disrupt, etc.). The cloud mask is currently manual.
225 These corrections are essential for any user to be able to apply their own specific aerosol
226 preprocessing without errors linked to the instrument itself or the weather.
- 227 (iii) Level 2 products (L_2) provide processed lidar data including: saturation correction, background-
228 sky correction, geometrical form factor correction and gluing between high and low-energy
229 channels. These products also provide the aerosol optical properties and their corresponding
230 uncertainties.

231 4.2. L_0 to L_1 processing chain

233 Each instrument is equipped with an acquisition system provided by the Licel firm. The description of the
234 acquisition program producing output files in Licel format can be downloaded at
235 http://licel.com/raw_data_format.html. This process concerns three main sources of interferences: (i) Detection-
236 related interferences, (ii) Acquisition problems and (iii) Interferences linked to the lidar environment.

237 Any significative step of this process is tagged in the L_1a output files to identify the corrections applied.

238 4.2.1. Detection interferences

239 Detection-related interferences can generally be linked to electromagnetic disturbances, which can occur in
240 three different ways.

241 (i) An increased background signal concerning variable altitude ranges can impact the complete profile as
242 shown in **Figure 4a**. This disturbance affects one or several channels across a significant altitude range, making
243 the data acquisition unusable and requiring its withdrawal. This is one of the reasons files of a few minutes are
244 created. The strong disturbance in the signal enabled to fully automatize their detection. Notably, obturated
245 detectors are more sensitive to these disruptions. Experience proved that they are directly related to the use of cell
246 phones and Talky-Walkies. These instruments have been banned from the instrumental rooms during the
247 measurements, significantly decreasing the frequency of these cases.

248 (ii) A second electronic problem often encountered comes from electronic gating. In fact, if a high and low-
249 energy channel coexist, a peak can be observed on the low-energy channel raw signal, at the gated altitude of the
250 high-energy channel (**Figure 4b**). This parasite peak usually appears on 2 consecutive range bins. This type of
251 problem occurs when the detectors are obturated and can have a significant impact on the measurement. It is
252 therefore necessary to remove the corresponding values and replace them by an averaged value between the
253 previous and following range bins.

254 (iii) The third detection disturbance corresponds to a sudden peak of the signal on a single randomly located
255 range bin. They only concern LiO_3S and LiO_3T . The consequence on the nighttime averaged profile is shown on
256 **Figure 4c**. Generally, the intensity of these spurious peaks is consistent and significantly higher than the
257 atmospheric background noise. They are easily identified when the intensity of the received signal is much lower

258 and become negligible with a stronger signal. However, there is an intermediate zone where the intensity of the
259 received signal is close to the intensity of these peaks, making their detection more challenging. They are replaced
260 by an averaged value.

261

263 4.2.2. Acquisition problems

264 The acquisition program computes 1- or 2-minute integrated profiles, depending on the instrument. However,
265 with this acquisition program, the measurement cannot be stopped at the end of the current cycle. As a result, the
266 last file is generally shorter than the others and must be removed to guarantee consistent measurements.

267 Another issue was a time desynchronization of several minutes between the computer acquisition clocks in
268 2021, revealing a configuration default in the corresponding Network Time Protocol time servers. Time differences
269 could increase up to 15 minutes between the different computers. This default has been fixed and a time-correction
270 is applied for signals between 2012 and 2021.

271 Last, interaction between the different lidars working at the same time and emitting the same wavelength can
272 also lead to interferences and disturbances on sensitive channels. To avoid this issue, the lasers are synchronized
273 out of phase. However, errors with this offset can lead to files with a higher sky background than others. These
274 files are removed.

275 4.2.3. Disturbance from clouds.

276 The SNR is most sensitive to the presence of low-altitude clouds. These clouds strongly absorb the emitted
277 photons and lead to high extinction levels and weak SNRs. They must be removed. High-altitude cirrus clouds can
278 also be removed if stratospheric aerosols are studied. Cloud-detection can be both automatic and/or manual. An
279 automatic detection of low clouds under 5 km height has been developed and can be used from 2019 up to now
280 using data from a Campbell CS135 ceilometer set up at the Maïdo facility in 2019. A manual cloud screening is
281 done for any remaining cirrus or low clouds. Automatization is in progress for this time-consuming work.

282 4.3. L₁ to L₂ processing chain

283 The goal of this second processing chain is to retrieve vertical profiles of aerosol optical products. It involves
284 several key steps.

285 4.3.1. Saturation correction

286 Saturation affects photomultiplier tube detectors with an acquisition card in photocounting mode. It concerns
287 the lower layers of the atmosphere and appears when the number of backscattered photons overcomes the capacity
288 of the acquisition card to discriminate them individually. Therefore, the backscattered signal is attenuated in the
289 corresponding layers. On the contrary, acquisition in analog mode is not affected by saturation, but has a weaker
290 SNR.

291 One solution is to combine (namely glue) analog and photocounting channels if both are available, which is
292 not always the case for our instruments.

293 The second option is to compare high and low-energy channels (or analog and photocounting channels if
294 available) in the lower layers and apply a dead-time correction to the photocounting channel using the Müller
295 equation. This is the solution we adopted for Maïdo lidars concerning aerosol, which is similar to what is done
296 for ozone and temperature processings (Leblanc et al., 2016a; Leblanc et al., 2016b). The dead-time parameter
297 (τ_d) corresponds to the minimum time for discriminating two consecutive photons. Our photocounting modes are
298 non-extensive, which means that the dead-time value is independent from the number of backscattered photons.
299 We then apply the Müller equation (Müller, 1973):

$$300 \quad S_{desat} = \frac{S_{sat}}{1 - \tau_d \cdot \frac{c}{2 \cdot \delta_z \cdot L} \cdot S_{sat}} \quad (1)$$

301
302 With S_{sat} (resp. S_{desat}) corresponding to the saturated (resp. desaturated) detected signal in number of photons
303 per second, δ_z the vertical resolution in meters, c the light celerity in meters per second, and L the number of shots.

304 A value of $\tau_d = 3.7ns$ is chosen. This value is the one recommended by Licel manufacturers and was confirmed
305 after several experimental tests which are available in a summary document.

306 **4.3.2. Background correction**

307 The background sky signal (S_{BC}), is one of the main sources of noise affecting the SNR. It corresponds to: (i)
308 the detector noise, and (ii) the natural light emitted by the atmosphere and can be affected by the presence of the
309 moon during the night. The value of this signal is supposed to be constant with the altitude but in practice it
310 sometimes follows a linear variation due to the effect of the signal induced noise on the detector. Our instruments
311 are not equipped with any pre-trigger. Our method to calculate the (S_{BC}) value consists in performing a linear
312 regression or an averaging of the desaturated signal in an altitude range high enough to neglect the impact of the
313 backscattered signal compared to the (S_{BC}), typically between 80km and 120km.

314 **4.3.3. Geometrical form factor correction**

315 The overlap function $F(z)$ or crossover function is one of the major sources of uncertainties for ground-based
316 lidar measurements. It describes the fraction of the laser beam cross section contained by the telescope field of
317 view as a function of range. Its values vary between 0 (blind zone, no overlap) and 1 (full overlap). Originally,
318 Maïdo lidars were designed to study the high troposphere and the stratosphere and at these altitudes, the full overlap
319 is obtained, which is why there has not yet been a more specific study on these instruments.

320 Should this parameter not be corrected, the received lidar signal would be attenuated between the blind zone
321 and the full overlap, leading to incorrect optical values. Two approaches can be followed to determine this
322 parameter. (i) A theoretical calculation using equations found in Measures (1984) can be performed. However, it

323 implies the knowledge of several optical parameters which can vary over the timeseries, and different equations
324 must be used for coaxial and biaxial systems. (ii) The second and most common approach is experimental and
325 implies the use of horizontal measurements (Chazette et al., 2017). In fact, considering a constant and homogenous
326 atmosphere along the line of sight, a linear regression can be performed in an altitude range high enough to be far
327 from the full overlap. The difference between the logarithm of the signal and this linear regression gives an accurate
328 estimation of $F(z)$.

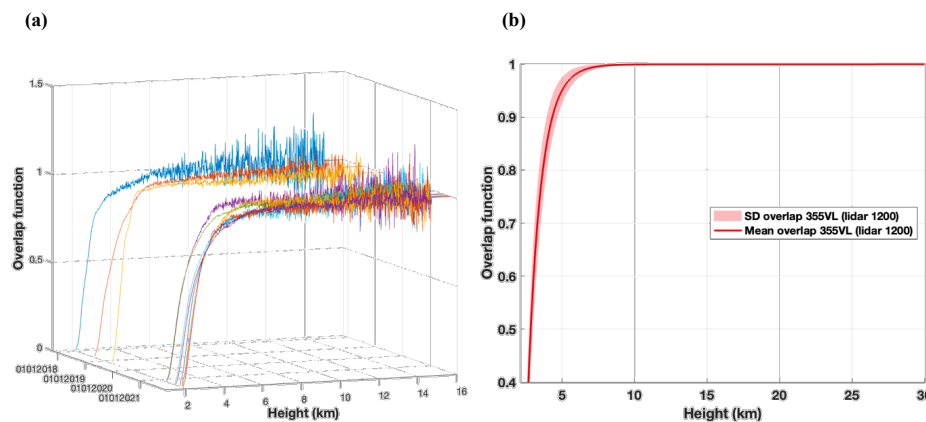

$$329 \quad F(z) = \exp(\ln(S_2(z)) - y(z)) \quad (2)$$

330 With S_2 the desaturated, background corrected, and range corrected lidar signal, $y(z)$ the linear regression and
331 z the altitude range.

332 It is physically impossible for these research instruments to measure horizontally. Therefore, the experimental
333 approach using vertical measurements (instead of horizontal) in aerosol-free conditions was performed to correct
334 overlap for the very low and low channels of the lidar 1200. As of today, no overlap correction was needed for the
335 LiO3S (full overlap under 10km) and LiO3T (full overlap between 3 and 4km).

336 **Figures 5a and 6a** reveal the variability of the overlap function over the time-series for both Li1200 VL and
337 L channels. This variability can be explained by slight misalignments of the lidar. Indeed, given the important
338 number of optical elements between the laser and the emission point, the risk of misalignment, even minor, is
339 significant. **Figures 5b and 6b** show the mean and standard deviation (std) of the overlap function from an
340 exponential regression. The small values of std are an indicator of a low-varying function, a result that allows to
341 use a unique overlap function rather than different functions for different periods. The estimated altitude of full
342 overlap was 10 km for the Very Low channel and 15k m for the Low channel.

343

344

345

Figure 5: Li1200 VL channel. (a) Time series of overlap functions, (b) Mean and standard deviation of the overlap function.

346

347

Figure 6: Li1200 L channel. (a) Time series of measured overlap functions, (b) Mean and standard deviation of the exponential regression of the overlap function.

348

4.3.4. Smoothing

349

Smoothing is applied on the lidar signal to increase the accuracy of the retrieved aerosol profiles. For the three time-series, smoothing was achieved using a low-pass filter with a Blackman window (Blackman and Tukey, 1958). The number of points for the filter was altitude-dependent and channel-dependent.

352

$$S_{filt}(z) = S_2(z)/F(z) * \frac{coef}{\sum coef} \quad (3)$$

353

$$coef(n) = 0.42 - 0.5 * \cos\left(\frac{2\pi n}{W-1}\right) + 0.08 * \cos\left(\frac{4\pi n}{W-1}\right), 0 \leq n \leq M-1 \quad (4)$$

354

With S_{filt} the smoothed signal, S_2 the desaturated, background corrected, and range corrected lidar signal, M half the length of the window and W the weight of the filter.

356

Figures 7a-c represent the new vertical resolution for each channel of each instrument. Two methods can be used to estimate vertical resolution after smoothing: (i) Impulse response method and (ii) Digital Filter. The latter was chosen for these time-series. It involves the mathematical calculation of the filter transfer function, using a cut-off frequency at -3dB (NDACC_resolDF, (Leblanc et al., 2016)).

360

361

362

Figure 7: NDACC vertical resolution of (a) LiO3S, (b) Li1200, and (c) LiO3T.

363 4.3.5. Gluing near and far-range channels

364 High and low energy channels were combined for the LiO3S and the Li1200 using the gluing method of the
 365 square sinus and cosinus functions. The altitude range chosen for the gluing corresponded to a region where the
 366 high energy channel was not affected by electronic distortions and the low energy channel was not affected by too
 367 much noise.

$$368 \left\{ \begin{array}{l} v1(z) = 0, \quad z < altmin \\ v1(z) = \sin^2\left(\frac{0 \rightarrow 1}{n} * \frac{\pi}{2}\right), \quad altmin \leq z \leq altmax \end{array} \right. \quad (5)$$

$$369 \left\{ \begin{array}{l} v2(z) = 1, \quad z < altmin \\ v2(z) = \cos^2\left(\frac{0 \rightarrow 1}{n} * \frac{\pi}{2}\right), \quad altmin \leq z \leq altmax \end{array} \right. \quad (6)$$

370 With n the number of range bins between $altmin$ and $altmax$, $v1$ the vector to apply to the high energy channel
 371 and $v2$ the vector to apply to the low energy channel.

372 The channels glued and used for inversion were: (i) 355VL + 355L + 355M + 355H and 355L + 355M + 355H
 373 and 355M + 355H for the Li1200, and (ii) 355H + 355M for the LiO3S. Each of these glued channels is available
 374 in the L_{15} files. Inversion was applied for each glued channels and corresponding optical products can be found in
 375 the L_2 files.

376 4.3.6. Calibration depolarization value for the LiO3T

377 Polarization channels enable to detect changes in the backscattered polarization state produced by the
 378 atmospheric particles. The laser provides quasi pure linear polarization. A polarizing cube beam splitter transmits
 379 the received linear polarized light and reflects the received cross polarized light. It is necessary to determine the
 380 polarization calibration factor before combining the two signals (Biele et al., 2000).

381 Three methods can be used: (i) Rayleigh calibration method (Behrendt and Nakamura, 2002), (ii) $\pm 45^\circ$ or $\Delta 90^\circ$
 382 calibration methods (Freudenthaler, 2016), and (iii) 3 signals (total, cross and parallel) method (Reichardt et al.,
 383 2003). While methods 2 and 3 provide the smallest uncertainties, method 1 can be used retrospectively if no total
 384 channel existed. The apparent Volume Linear Depolarization Ratio (VLDR*) can then be calculated following:

$$385 \quad 386 \quad VLDR^* = \frac{K}{\eta^*} * \frac{S_r}{S_t} \quad (7)$$

387
 388 With t and r the respective transmitted and reflected parts of the signal S , η^* the apparent calibration factor and K
 389 the calibration factor correction parameter.

390 The VLDR can then be computed using the polarization crosstalk parameters for the transmitted and reflected
 391 signals ($G_{t,r}$ and $H_{t,r}$):

$$392 \quad 393 \quad VLDR = \frac{VLDR^*(G_t + H_t) - (G_r + H_r)}{(G_r - H_r) - VLDR^*(G_t - H_t)} \quad (8)$$

394
 395 The total signal will also be reconstructed following:

396

$$S_{total} = \frac{\eta^* H_r S_t - H_t S_r}{H_r G_t - H_t G_r} \quad (9)$$

398

399 The aerosol backscatter β_a will then be deduced from the total signal S_{total} using Klett inversion. The backscatter
 400 ratio R will be calculated following:

401

$$R = \frac{(\beta_a + \beta_{mol})}{\beta_{mol}} \quad (10)$$

403

404 Finally, the Particle Linear Depolarization Ratio ($PLDR$) can be computed following:

405

$$PLDR = \frac{(1 + LDR_{mol}) * VLDR * R - (1 + VLDR) * LDR_{mol}}{(1 + LDR_{mol}) * R - (1 + VLDR)} \quad (11)$$

407

408 In our case, we used the Rayleigh method before 2017 and the 3 signals method after 2017. We used a linear
 409 molecular depolarization ratio (LDR_{mol}) of 0.00398 at 532nm (Behrendt and Nakamura, 2002) to estimate η^* , and
 410 a K factor of 1 to estimate $VLDR^*$. Crosstalk parameter values were considered ideal: $G_t = 1$, $H_t = 1$, $G_r = 1$ and
 411 $H_r = -1$.

412 4.3.7. Optical products: Klett inversion

413 This step is mandatory to retrieve aerosol optical properties from the detected lidar signals. However, it implies
 414 to resolve an order 1 Bernoulli equation with several unknown parameters. Several methods exist such as: (i) One
 415 or two-components Klett inversion (Klett, 1981, 1985), (ii) Raman inversion (Ansmann et al., 1990, 1992), and
 416 (iii) a synergistic method using Klett inversion and sunphotometer measurements to evaluate the lidar ratio (Raut
 417 and Chazette, 2007).

418 Because Raman channels have currently a very low SNR, they are not included in this work and the two-
 419 component Klett inversion method was chosen for the three systems. It implies to determine *a priori* constant
 420 value of Lidar Ratio (LR) and a clean, aerosol-free zone in the atmosphere (Rayleigh zone). Details about the
 421 elastic two-component algorithm from Klett are available in **Appendix A**.

422 The solution proposed in Appendix A is:

423

$$\beta(\lambda, z) = \beta_a(\lambda, z) + \beta_m(\lambda, z) = \frac{S_2(\lambda, z) \cdot \exp\{2 \cdot \int_z^{z_{ref}} \left(\frac{LR_a(\lambda, z')}{LR_m(\lambda, z')} - 1 \right) \cdot \alpha_m(\lambda, z') dz'\}}{\beta(\lambda, z_{ref}) + 2 \cdot \int_z^{z_{ref}} LR_a(\lambda, z') \cdot S_2(\lambda, z') \cdot \exp\{2 \cdot \int_{x'=z}^{z_{ref}} \left(\frac{LR_a(\lambda, x')}{LR_m(\lambda, x')} - 1 \right) \cdot \alpha_m(\lambda, x') dx'\} \cdot dz'} \quad (12)$$

425

426 With \mathbf{a} (resp. \mathbf{m}) the particular (resp. molecular) contribution, $\alpha(\lambda, z)$ (resp. $\beta(\lambda, z)$) the summed molecular and
 427 particular extinction (resp. backscatter), and LR the Lidar Ratio. S_2 corresponds to the range-corrected, sky
 428 background corrected and desaturated signal. However, the signal used in this study for the inversion algorithm is
 429 smoothed as explained in paragraph 4.3.4. and could be glued (Li1200, LiO3S) or recombined (LiO3T).

430 Several unknown parameters must be determined:

431 (i) To retrieve the \mathbf{LR}_a , we chose a constant LR value of 50 sr for the three instruments to be consistent
432 between the time-series and to target the most frequent aerosol types. Moreover it enables easier
433 comparisons with satellite data such as CALIOP products (Cattrall et al., 2005).

434 (ii) The equation used to retrieve the molecular extinction was (Bates, 1984):

$$435 \quad \alpha_m(\lambda, z) = \frac{P}{k * T} * \frac{4.02 \cdot 10^{-28}}{\lambda^{4+(0.389\lambda+0.09426\lambda^{-1}-0.3228)}} \quad (13)$$

436 With k corresponding to the Boltzmann constant. Atmospheric pressure P and temperature T were
437 retrieved from the Arletty AERIS product (<https://www.aeris-data.fr/>), relying on data from the
438 European weather forecast model ECMWF (European Centre for Medium-Range Weather Forecasts),
439 and producing interpolated data every 6h around Maïdo observatory (Hauchecorne, n.d.).

440

441 The molecular backscatter was then computed following:

442

$$443 \quad \beta_m(\lambda, z) = \alpha_m(\lambda, z) * \frac{3 * K_f}{8\pi} \quad (14)$$

444 The King factor's value (K_f) is considered equal to 1 (King, 1923), and $\frac{3}{8\pi}$ corresponds to the \mathbf{LR}_m .

445 (iii) The last step was to determine for each daily measurement and each channel a reference 'Rayleigh'
446 zone z_{ref} supposed free of any aerosols.

447

448 4.3.8. Raman and 1064 nm channel issues

449 Klett inversion brings the problem of considering a lidar ratio constant with height. In fact, a single aerosol
450 plume is often made of several layers of particles with heterogenous backscattered lidar signals. Raman inversion
451 is one solution to deduce a vertical profile of lidar ratio from elastic and Raman channels. However, our Raman
452 channels have a poor SNR and are not usable for stratospheric or high tropospheric aerosols. The retrieval of
453 aerosol optical products using Raman inversion for low-energy channels (low and middle troposphere) is still
454 ongoing. There is also a misalignment issue for the 1064-nm channel leading to a poor SNR. This channel is
455 currently unexploitable.

456 5. Quality assessment

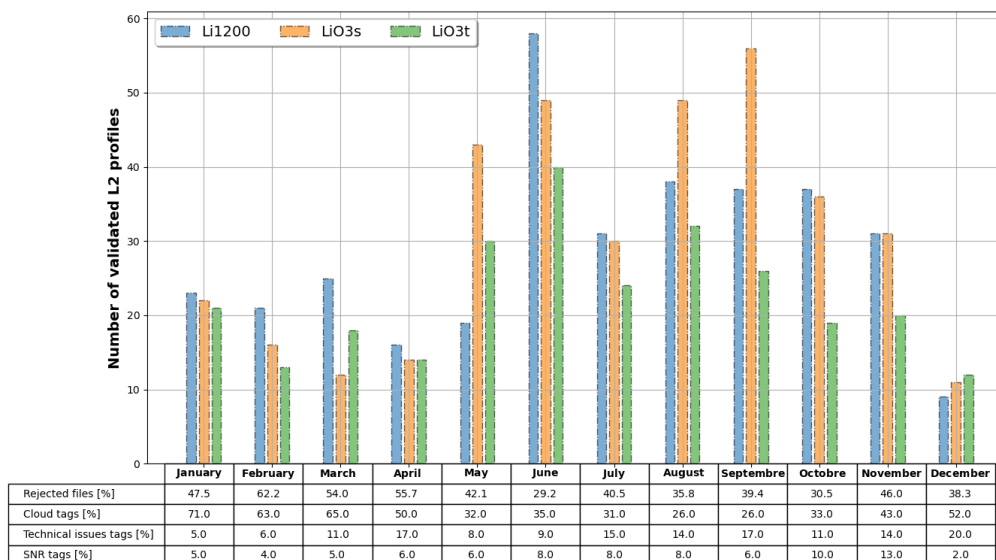

457

458 5.1. Database statistics

459 A total of 1737 nighttime measurements were preprocessed between 2013 and 2023: 710 files for Li1200, 534
460 files for LiO3S, and 493 files for LiO3T. Notably, the mean percentage of rejected files was higher for Li1200
461 (52.7%), than LiO3T (44.8%) and LiO3S (32.7%). **Figure 8** shows the cumulated monthly number of validated
462 L₂ profiles for each instrument, the monthly mean number of rejected files and corresponding tags (cloud detection,
463 technical issue, low SNR). It should be noted that most observations were made during the May to November
464 period (austral winter, dry season) compared to the December to April period (austral summer, wet season), which
465 is consistent with the higher cloud and rain occurrence during the wet season. The mean percentage of validated
466 L₁ files was 62.4% during the dry season and 48.5% during the wet season. The lower frequency of measurements

467 in January, July, August, and December also concurs with two important holiday periods. The frequency of
 468 technical issues and lower SNR is statistically higher during the months with a greater number of measurements.

469

Figure 8: Number of validated files for the three instruments in the period 2013-2023. In the table below, mean percentage of rejected files and tagged files for each month.

470

471 5.2. Instrumental capabilities

472

The gluing technique allowed to determine different altitude ranges for each lidar depending on the channels available. **Table 1** provides a summary of the theoretical instrumental performances in terms of altitude ranges. Apart from the number of glued channels, other parameters can influence the maximum altitude (SNR) or the minimum altitude (Overlap, SNR) of the validated L_2 vertical profile. The LiO3T at 532 nm is ideal to investigate the low and mid troposphere. The high troposphere and stratosphere can be studied at 355 nm (Li1200 and LiO3S) or 532 nm (LiO3T – from 2017 until now).

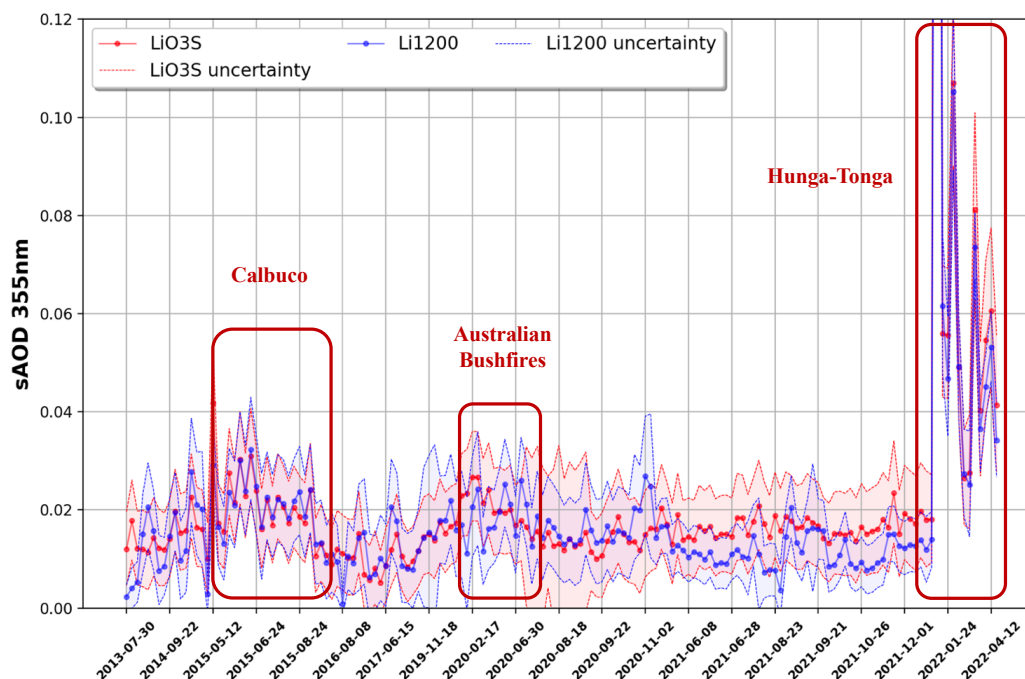

478

5.3. Instrumental intercomparison

479

In this study, we performed a comparison between the three instruments to detect any major discrepancies using the Stratospheric Aerosol Optical Depth (sAOD) between 17 and 30 km. **Figure 9** displays the time-series of sAOD at 355 nm (Li1200 and LiO3S) for concomitant measurements and corresponding uncertainties. There is a good overall consistency between the two instruments. The differences between the two time-series could be the consequence of technical modifications (channel addition, optimization, misalignments). Three peaks periods of high sAOD values can be identified: the emission of volcanic aerosols in the stratosphere during the Hunga-Tonga eruption in 2022 (Kloss et al., 2022; Baron et al., 2023; Sicard et al., 2023), the Calbuco volcanic eruption in 2015 (Bègue et al., 2017) and the Australian bushfires in 2020 (Khaykin et al., 2020). Higher differences in 2021 could be the consequence of repeated misalignments for the Li1200.

487

488

489

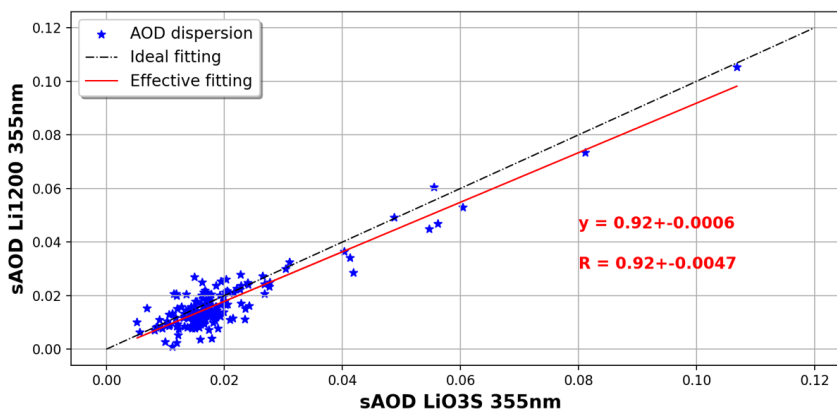

Figure 9: Nighttime AOD (17 to 30 km layer) at 355 nm, from the Li1200 (red) and LiO3S (blue) (concurrent measurements) with corresponding uncertainties (dashed colored lines). Exceptional events circled in red. The horizontal timeline is not linear: one date out of eight is represented for visual purposes.

490

491

492

The dispersion of sAOD values is represented in **Figure 10**. The sAOD at 355 nm varies between 0.001 and 0.107 for LiO3S and Li1200, with a mean of 0.019 ± 0.012 and 0.017 ± 0.012 , respectively. A good correlation is found between the two lidars (correlation $R = 0.924 \pm 0.005$).

493

494

Figure 10: Dispersion of the AOD (17 to 30 km layer) at 355 nm, between the Li1200 and LiO3S. The red line represents the theoretical linear regression.

495

496

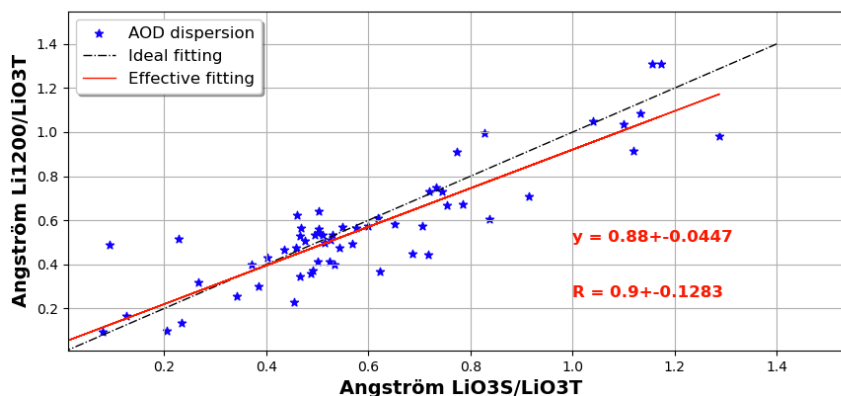

The correlation between the two instruments at 355 nm in terms of extinction values is higher above 17 km but lower from 10 to 17 km (**Appendix D, Figure D1**). In fact, for the Li1200: (i) low energy channels were added in

497 2017, **(ii)** there were changes in the minimal altitude of detection for the 355M channel, and **(iii)** this instrument
498 had many misalignments and underwent several optical upgrades, leading to modifications of the overlap function.

499 For further retrospective trend studies, it is important to note that the LiO3S has been the most stable instrument
500 throughout the time-series and is considered the reference instrument at 355 nm. However, data from the Li1200
501 can be used to fill the gaps of the LiO3S database depending on the altitude range targeted, but also for specific
502 case studies with the need to retrieve optical products for the middle and low troposphere.

503 The same analysis was performed for the LiO3T. To compare the two wavelengths, Ångström exponents (AE)
504 were computed between the LiO3T (532 nm) and alternatively the LiO3S (355 nm) and Li1200 (355 nm). **Figure**
505 **11** shows the dispersion of AE values. The order of magnitude of AE values varies between 0.0794 and 1.288 with
506 a mean of 0.56 ± 0.29 and 0.54 ± 0.28 , respectively. Again, a good correlation is found between both datasets
507 ($R = 0.901 \pm 0.128$). These values also demonstrate the variability of stratospheric aerosol size distribution
508 between 17 and 30 km (Gobbi et al., 2007; Burton et al., 2012).

509

510 **Figure 11: Dispersion of the AE (17 to 30 km layer) between 355 and 532 nm. The black line**
511 **represents the theoretical linear regression and the red line the actual linear regression.**

511

512 5.4. Main sources of uncertainties

513 The total uncertainty budget of each lidar is described in **Appendix B**. Four sources of uncertainty were
514 propagated in quadrature (Sicard et al., 2009; Rocadenbosch et al., 2010): **(i)** uncertainty due to the Rayleigh
515 calibration value (u_{altref}), **(ii)** uncertainty due to the lidar ratio value (u_{LR}) with a distinction between LR , *top* and
516 LR , *bottom* defining the respective upper and lower error bars, **(iii)** uncertainty due to the SNR vertical distribution
517 (u_{SNR}), **(iv)** and uncertainty due to the SNR value at the calibration altitude ($u_{SNR,altref}$). **Figures 12a-12c**
518 represent for three case reports the importance of each uncertainty relatively to the total backscatter in percentage,
519 and **Figures 12d-12f** represent the corresponding propagated total backscatter uncertainty for the three
520 instruments.

521 In **Figures 12a-12c**, the behavior of the uncertainties u_{altref} (blue curves) and $u_{SNR,altref}$ (green curves) is
522 stable over the different altitude ranges. Notably, u_{altref} comes from the 5% uncertainty of the molecular

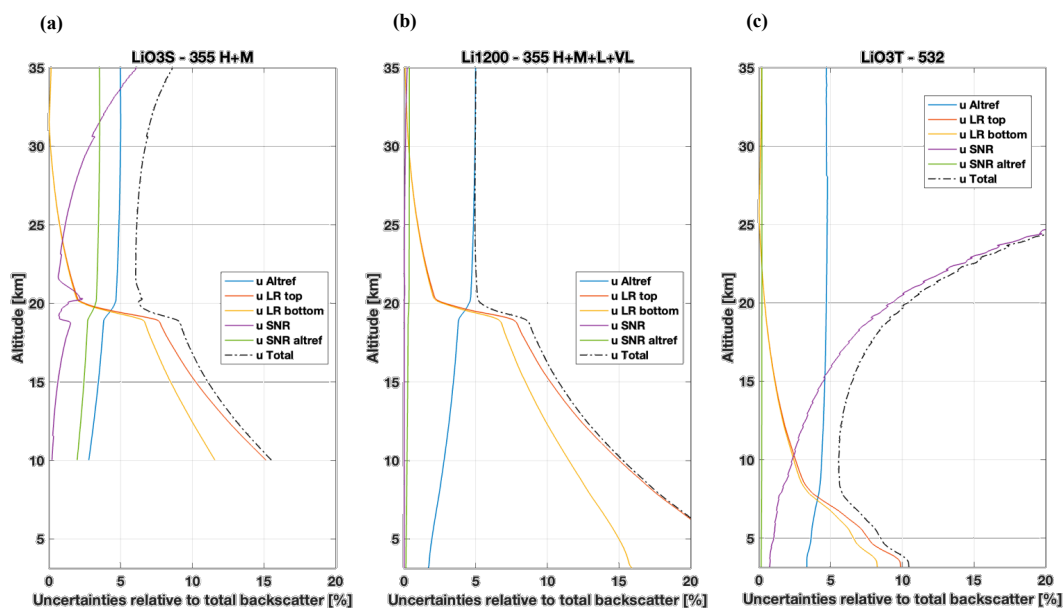

523 backscatter, which determines the lower threshold for the total uncertainty. The u_{SNR} uncertainty (purple curves)
524 is strongly influenced by the altitude, with minimal values at lower altitude ranges where the lidar signal is stronger,
525 and values increasing with the altitude. In fact, lidar signals are filtered before inversion, making u_{SNR} the
526 predominant error at higher altitude levels. Oppositely, the u_{LR} uncertainty (orange and yellow curves) is the lowest
527 at the calibration altitude and increases in the lower levels, where it becomes predominant. The systematic
528 uncertainty on the LR value was set to 30% for this study. Therefore, the total uncertainty is the lowest in mid-
529 altitude ranges before increasing in lower and higher altitude levels. Sharp spikes in u_{LR} can be observed just
530 below 20km for the LiO3S and Li1200, and below 8 km for the LiO3T. They are linked to the presence of aerosol
531 plumes and emphasize the impact of aerosols on the uncertainty values in lower altitude levels.

532 For the LiO3S (H+M glued channel), the total relative uncertainty reaches 15% at 10 km, decreases down to
533 6% around 20 km, and increases up to 8% around 35 km. (**Figure 12a**). Without the aerosol layer, the minimum
534 error would be reached around 15 km. For the Li1200 (H+M+L+VL glued channel), the total relative uncertainty
535 reaches 20% at 7 km and decreases down to 5% from 20 km up. (**Figure 12b**). The uncertainty due to the SNR is
536 very low compared to the LiO3S, as this instrument is designed to reach very high-altitude levels, and the signal
537 used for inversion is made of four filtered signals with complementary vertical capacities. Without the aerosol
538 layer, the minimum error would be reached around 17 km. For the LiO3T, the total relative reaches 10% at 4 km,
539 decreases down to 6% around 8 km, and increases up to 20% around 25 km. (**Figure 12c**). The uncertainty due to
540 the SNR is higher than the previous lidars because this instrument is designed for tropospheric measurements.

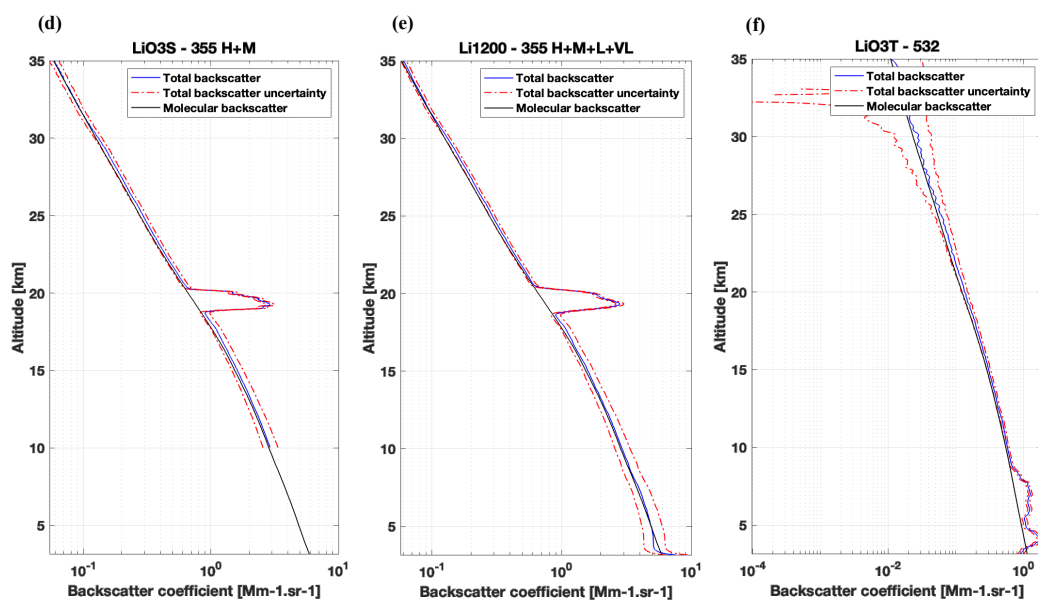

541

542

544

Figure 12: Upper row: random cases showing the molecular backscatter (black), the backscatter coefficient (blue) and its apparent uncertainty (red dotted line) for the (a) LiO3S (25/01/2022), (b) Li1200 (25/01/2022) and (c) LiO3T (25/09/2017). Lower row: corresponding relative uncertainties for the (d) LiO3S, (e) Li1200 and (f) LiO3T.

545

546

547 In Figures 12d-12f, the three instruments demonstrate their capacity to detect aerosol layers with relatively
 548 low error rates and a high resolution. Figures 12d-12e specifically show their ability to identify variations within
 549 the aerosol layer between 18 and 20 km. For the LiO3T (Figures 12f), the aerosol layer between 4 and 8 km is
 550 exceptionally well defined, with relatively low error values. Apart from these aerosol layers, the molecular

551 backscatter (in black) tends to align closely with the uncertainty of the total backscatter (in red). In fact, background
552 aerosols are characterized by very low backscatter and extinction values, leading to the relatively high sAOD
553 uncertainties observed in **Figure 9**: higher for background aerosols but lower for cases with a stronger aerosol
554 load, such as from Australian fires or volcanic aerosols. Focusing on the uncertainty specific to aerosol backscatter
555 (rather than the total) is essential to improve the uncertainty analysis, along with a statistical analysis of the dataset
556 to minimize disruptions caused by transient aerosol events. Time-series of aerosol backscatter relative total
557 uncertainties were computed for the three instruments and the corresponding mean and standard deviation are
558 represented **Figures 13a-c**. Values are high and easily reach 100% for the three instruments because of the very
559 low values of aerosol backscatter coefficients above Maïdo observatory. The mean uncertainty is the lowest for
560 the LiO3S between 18 and 25 km (64.4 ± 31.6 %). It increases under 18 km and above 25 km with relative
561 uncertainty values reaching more than 100% due to the very weak aerosol backscatter values at these altitude
562 ranges. The mean uncertainty for the Li1200 is also the lowest between 18 and 25 km (50.3 ± 29.0 %). It increases
563 under 18 km and above 25 km with relative uncertainty values relatively lower than the LiO3S due to a lower
564 SNR, and the presence of low and very low channels detecting aerosol plumes at lower altitudes. The LiO3T
565 exhibits a low relative uncertainty below 20 km, it varies around 69.1 ± 42.7 %. The strong increase above 20 km
566 is essentially explained by the very low SNR for this instrument at these altitude ranges.

567

568

569

570

571

572 6. Data availability

573

574

575

576

Raw L_0 files, cleaned L_1 files and processed L_2 files with optical products are generated locally. L_0 files are made of 1-minute integrated raw files in licel format. L_1 products contain 1-minute integrated time-series and overnight averaged cleaned signals in mat file format and netcdf format. L_2 products in mat file format contain overnight averaged processed signals, as well as range-corrected signals for Raman channels. L_2 products are also

577 computed in netcdf format following NDACC guidelines in anticipation for a future NDACC label request. **Table**
578 **CI** in **Appendix C** summarizes the optical products and other variables available in these L₂ netcdf files.

579 Each of these files is available on request in our local datacenter by FTP (<ftp://tramontane.univ-reunion.fr/>). L₁
580 and L₂ files are currently available at <https://doi.org/10.26171/rwcm-q370> (Gantois et al., 2024). Mat files and
581 netcdf files with L₂ data will soon be available on AERIS database, but only L₂ netcdf files will be openly
582 accessible.

583 7. Summary

584 This study supports the first ever long-term time-series of multiwavelength aerosol optical properties generated
585 from three lidars operating at the Observatory of Atmospheric Physics of La Réunion (OPAR) since 2013. A full
586 description of the technical specifications for the three instruments is provided, as well as details about the
587 preprocessing and processing methods used to produce the different dataset levels. The three time-series consist
588 in vertical profiles of aerosol elastic backscatter and extinction coefficients at 355 and 532 nm, and linear
589 depolarization ratio at 532 nm above Maïdo observatory (2160 m asl, west side of Reunion Island, Southern
590 Hemisphere) from 2013 until now.

591 The preprocessing step required manual cleaning of more than 1700 files, and the highest frequency of cloud
592 occurrence resulted in a lower number of validated profiles during the wet season. Data processing methods and
593 the Klett inversion technique chosen for this work are detailed and referenced. One issue concerns the random
594 misalignments and technical modifications for the three instruments leading to highly variable parameters such as
595 the geometrical form factor. As an alternative to the Klett method, the Raman inversion technique has been
596 attempted but failed for stratospheric and high tropospheric levels due to a poor SNR.

597 Intercomparison between the three instruments show a good correlation in terms of sAOD values. The
598 uncertainty analyses reveal a strong influence of the LR value in the low-altitude ranges and a strong influence of
599 the SNR in the high-altitude ranges. Uncertainty values relative to the total backscatter coefficient are low for the
600 three instruments. Uncertainty values relative to the aerosol backscatter coefficient are high for the three
601 instruments because of the very low aerosol backscatter coefficient values generally observed above Maïdo
602 observatory. Among the three instruments, the LiO3S stands out as the most stable (less misalignments, less
603 technical modifications) and should be considered the reference instrument at 355 nm. However, data from the
604 Li1200 can be used to fill the gaps of the LiO3S database and for specific case studies.

605 Appendices

606 Appendix A

607 The equation describing the desaturated lidar signal can be written as:

$$608 \quad S_{desat}(\lambda, z) = C(\lambda) \cdot \frac{F(z)}{(z - z_0)^2} \cdot \left\{ \sum_i \beta_i(\lambda, z) \right\} \cdot \left\{ \exp \left[-\frac{2}{\cos(\theta)} \cdot \sum_i \tau_i(\lambda, z_0, z) \right] \right\} + S_{bck}(\lambda) \quad (A1)$$

609 With C the instrumental constant, F the overlap function, β_i the backscatter coefficient of the component i , τ_i the
610 integrated extinction coefficient of the component i between altitude z_0 and z , and S_{bck} the background signal.

611 The range-corrected, sky background corrected and desaturated signal can then be considered:

612

$$S_2(\lambda, z) = [S_{desat}(\lambda, z) - S_{bck}(\lambda, z)] \cdot (z - z_0)^2 \quad (A2)$$

614

615 Derivation of the logarithm of S_2 leads to:

616

$$\frac{\delta[\ln(S_2)]}{\delta z} = \frac{1}{\beta(\lambda, z)} \cdot \frac{\delta[\beta(\lambda, z)]}{\delta z} - 2 \cdot LR_a(\lambda, z) \cdot \beta(\lambda, z) - 2 \cdot \alpha_m(\lambda, z) \cdot \left(1 - \frac{LR_a(\lambda, z)}{LR_m}\right) \quad (A3)$$

618

619 With \mathbf{a} (resp. \mathbf{m}) the particular (resp. molecular) contribution, $\alpha(\lambda, z)$ (resp. $\beta(\lambda, z)$) the summed molecular and
 620 particular extinction (resp. backscatter), and LR the Lidar Ratio:

$$LR_a(\lambda, z) = \frac{\alpha_a(\lambda, z)}{\beta_a(\lambda, z)} \quad (A4)$$

$$LR_m(\lambda, z) = \frac{\alpha_m(\lambda, z)}{\beta_m(\lambda, z)} = \frac{8\pi}{3} * K_f \quad (A5)$$

623 With K_f corresponding to the King factor's value.

624 The two-component solution of this Bernoulli equation is:

625

$$\beta(\lambda, z) = \beta_a(\lambda, z) + \beta_m(\lambda, z)$$

$$= \frac{S_2(\lambda, z) \cdot \exp\left\{2 \cdot \int_{z'=z}^{z_{ref}} \left(\frac{LR_a(\lambda, z')}{LR_m(\lambda, z')} - 1\right) \cdot \alpha_m(\lambda, z') dz'\right\}}{\frac{S_2(\lambda, z_{ref})}{\beta(\lambda, z_{ref})} + 2 \cdot \int_{z'=z}^{z_{ref}} LR_a(\lambda, z') \cdot S_2(\lambda, z') \cdot \exp\left\{2 \cdot \int_{x'=z}^{z_{ref}} \left(\frac{LR_a(\lambda, x')}{LR_m(\lambda, x')} - 1\right) \cdot \alpha_m(\lambda, x') dx'\right\} \cdot dz'} \quad (A6)$$

628

629 Appendix B

630 The uncertainty budget was determined from the Klett elastic one components inversion technique. Mathematical
 631 details can be found in (Rocadenbosch et al., 2010) for the total backscatter inversion uncertainty budget and
 632 (Sicard et al., 2009) for the two components inversion uncertainty budget.

633 The Klett inversion was applied to the filtered signal following (see section 4.3.4.):

$$S_{filt}(z) = \frac{S_2(z)}{F(z)} * \frac{coef}{\sum coef} \quad (3)$$

635 Considering $C = \frac{coef}{\sum coef}$ and $S_{geo}(z) = \frac{S_2(z)}{F(z)}$, the uncertainty of the filtered signal followed the equation:

$$u_{filt}(z) = \sqrt{\left[\frac{\partial S_{filt}(z)}{\partial S_{geo}(z)} \cdot u_{S_{geo}}(z)\right]^2 + \left[\frac{\partial S_{filt}(z)}{\partial C} \cdot u_C(z)\right]^2} = \sqrt{\left[C(z) \cdot u_{S_{geo}}(z)\right]^2 + \left[S_{geo}(z) \cdot u_C(z)\right]^2} \quad (B1)$$

637

638 **Table B1** is a summary of the Total-Backscatter analytical error bars to compute in Klett's backward inversion
 639 method.

Uncertainty source	Equation
Uncertainty due to the Rayleigh calibration value (u_{altref})	$u_{altref} = \left \frac{\beta_j}{\beta_N} \right ^2 \frac{U_N}{U_j} \sigma_{\beta_N}$
Uncertainty due to the lidar ratio value (u_{LR})	$u_{LR} = \left \pm p \frac{2\beta_j^2}{U_j} G_j + p^2 \frac{4\beta_j^3}{U_j^2} G_j^2 \right $ Where: $G_j = \sum_{i=j}^N w_i S_i U_i$
Uncertainty due to the SNR vertical distribution (u_{SNR}).	$u_{SNR} = \sqrt{\left(\frac{\beta_j}{U_j} \right)^2 \sigma_{U_j}^2 + \left(\frac{2\beta_j}{U_j} \right)^2 \sigma_{GU_j}^2}$ Where: $\sigma_{GU_j}^2 = \sum_{k=j}^N (w_k S_k)^2 \sigma_{U_k}^2$
Uncertainty due to the SNR value at the calibration altitude ($u_{SNR,altref}$).	$u_{SNR,altref} \approx \left \frac{\beta_j^2}{\beta_N U_j} \right \sigma_{U_N}$

640 **Table B1: Total-Backscatter analytical error bars from Klett's backward inversion method (from Rocadenbosch et al.,**
 641 **2010)**

642

643 With β_j the total backscatter at the altitude cell j , U_j the range-corrected signal at the altitude cell j , N the calibration
 644 altitude cell, σ_{U_j} the uncertainty if the range-corrected signal U , σ_{β_j} the uncertainty of the total backscatter, S_j the
 645 total lidar ratio.

646 The uncertainty of the total backscatter error bars u_{β_T} can then be written as:

647
$$u_{\beta_T} = \sqrt{u_{altref}^2 + u_{LR}^2 + u_{SNR}^2 + u_{SNR,altref}^2} \quad (B2)$$

653

654 **Author contributions.** DG conducted this study with the help of MS, GP, and VD. DG performed the processing
655 of the lidar measurements, the uncertainty analysis, prepared the figures and the manuscript. GP and MS both
656 contributed to the improvement of the text, figures, and uncertainty analysis of this manuscript. GP designed two
657 original softwares used for data processing, which were improved by DG. NM designed the lidar optical schemes.
658 TP and SGB were responsible for the LiO3S instrument and dataset, VD and NM were responsible for the LiO3T
659 instrument and dataset, and VD and GP were responsible for the Li1200 instrument and dataset. PH and EG
660 performed the lidar measurements and the instrumental maintenance and reviewed the technical aspects of this
661 paper. All co-authors contributed to reviewing drafts of this manuscript.

662 **Competing interests.** The authors declare that they have no conflict of interest.

663 **Acknowledgments.** The authors gratefully acknowledge Louis Mottet and Yann Hello, who are deeply involved
664 in the routine lidar observations at the Maïdo facility.

665 **Financial support.** The authors acknowledge the support of the European Commission through the REALISTIC
666 project (GA 101086690). OPAR is presently funded by CNRS (INSU), Météo France, and Université de La
667 Réunion, and managed by OSU-R (Observatoire des Sciences de l'Univers de La Réunion, UAR 3365). OPAR is
668 supported by the French research infrastructure ACTRIS-FR (Aerosols, Clouds, and Trace gases Research
669 InfraStructure – France) and by the French Center for Spatial Studies (CNES). The projects OBS4CLIM (Equipex
670 project funded by ANR: ANR-21-ESRE-0013), EECLAT and AOS (CNES) are acknowledged.
