**Abstract.** We performed experiments to constrain the effects of sulphur and oxygen fugacities on magma chamber and outgassing conditions of the La Palma 2021 eruption. Based on a series of controlled experiments on basanitic products carried out at 1040°C and 200 MPa, we show that sulphur addition affects the stabilities of amphibole and olivine, in particular at high  $fO_2$  and elevated S contents which together inhibit amphibole crystallization. We also show that the overriding control on S systematics is oxygen fugacity, with melts capable of dissolving from 1000 up to 8000 ppm S, depending on  $fO_2$ . Increasing the bulk S content increases the S content of the silicate melt up to ~ 2000 ppm for  $fO_2 < NNO+2$ , and 7000–8000 ppm at higher  $fO_2$ . Further increase in dissolved S is prevented by the buffering effects of either sulphide at low  $fO_2$  or anhydrite at high  $fO_2$ . Modelling shows that the observed  $CO_2/SO_2$  and  $H_2O/SO_2$  ratios of volcanic gas emissions during the eruption imply a pre-existing > 5 wt% exsolved fluid in the reservoir, with  $fS_2$  at ~ 0.1 MPa at  $fO_2$  above NNO. Our work confirms that basaltic magmas may coexist with a significant amount of excess fluid which in turn holds an important part of the sulfur budget emitted to the atmosphere.

**Keywords:** La Palma, sulphur solubility, basanite, sulphur degassing

## 1. Introduction

The 2021 Cumbre Vieja eruption on La Palma produced ~ 0.2 km<sup>3</sup> of alkali basalt over a three month period, with devastating impacts on the built environment and agricultural land (Bonadonna et al., 2022; Del Fresno et al., 2023a; González et al., 2019; Ubide et al., 2023; Dayton et al., 2024). La Palma is made up of two volcanic centres. The oldest is the Taburiente centre in the north and the presently active Cumbre Vieja centre in the south of the island (Carracedo et al., 2001 and references therein). The volcanic activity of Cumbre Vieja area began about 123,000 years ago, and its complex extends from N to S being mainly composed of single eruptive centers spread along fissures. The eruptive products belong to the alkaline series, with emission of alkaline basalts, basanites, trachybasalts, tephrites and phonolites (e.g., Carracedo et al., 2001). Prior to the 2021 eruption, several eruptions have been recorded over the last 500 years (about 8), all associated with explosive events on the summit, and effusive lava flows along the flanks (Carracedo et al., 2001). La Palma is part of the oceanic island basalt system of the Canary Islands, which is fed by a hotspot of presumed mantle origin probably influenced by the rotation of the African plate (e.g., Day et al. 2022 and references therein).

42 The 2021 eruption was accompanied by vigorous degassing of CO<sub>2</sub> and S gas species, which were measured  
 43 intermittently using a variety of sensors (e.g., Burton et al., 2023). Estimates of the quantity of the total SO<sub>2</sub>  
 44 emitted range from 1 to over 4 Tg (Albertos et al., 2023; Burton et al., 2023; Dayton et al., 2024; Hayer et  
 45 al., 2022). Melt inclusion analyses reveal an average pre-eruptive S content of ~ 3000 ppm (Castro and  
 46 Feisel, 2022; Burton et al., 2023; Dayton et al., 2024). Complete syneruptive degassing of this sulphur would  
 47 yield over 3 Tg of SO<sub>2</sub>, i.e., an amount within the range of estimated emissions. However, estimates of initial  
 48 CO<sub>2</sub> contents lie in the range 3–5 wt% (Burton et al., 2023), which is more than sufficient to saturate a  
 49 basanite magma (e.g. Jiménez-Mejías et al., 2021; Lo Forte et al., 2024) at crustal pressures (<1 GPa). Given  
 50 the likelihood of a pre-eruptive gas phase in the reservoir (Sandoval-Velasquez et al., 2023; Zanon et al.,  
 51 2024; Dayton et al., 2024) raises the question of how much sulphur was partitioned into it? In silicic magmas,  
 52 S is inferred to reside dominantly in the gas phase (e.g. Scaillet et al., 1998; Keppler, 1999).

53 Critical to understanding the behaviour of S in magmatic systems is to constrain their redox state or oxygen  
 54 fugacity ( $fO_2$ ), which exerts a major control on S solubility and partitioning (e.g., (Carroll and Rutherford,  
 55 1988; Luhr, 1990; Scaillet et al., 1998; Jugo, 2004; Moretti and Ottonello, 2005; O’Neill, 2021; Boulling  
 56 and Wood, 2023; Hughes et al., 2023). Knowing whether S goes into the fluid/gas or not is crucial for  
 57 interpreting the composition of volcanic gases at the surface, which are routinely measured for the purposes  
 58 of hazard assessment.

59 Our overall aim here is to develop understanding of S solubility and partitioning in mafic magmas with  
 60 hotspot and ocean-island basalt (OIB) affinities through a set of experiments on La Palma 2021 basanite in  
 61 which  $fO_2$  and the amount of S were varied. To this end, we reconstructed eruptive conditions at La Palma.  
 62 In particular, we focused on the amount of sulphur and its fugacity at pre-eruptive conditions in the reservoir  
 63 and in the fluid phase during eruptive outgassing.

## 64 2. Experimental technique

### 65 2.1 Starting material and apparatus

66 Basanite lapilli (1 Top/27-9-2021) from the 2021 eruption of La Palma were selected as the starting  
 67 material. The lapilli were finely ground using an agate mortar and then melted in a Pt crucible at  
 68 1400°C for 4 h at atmospheric pressure. These steps were repeated to obtain an homogeneous and  
 69 anhydrous glass. Homogeneity was verified using the Electron Micro Probe analyzer (EMPA). The  
 70 composition of the glass is reported in Table 1.

71 The experiments were performed with Internally Heated Pressure Vessels (IHPV) at the Institut  
 72 des Sciences de la Terre d’Orléans (ISTO), using as pressure media either Ar or a H<sub>2</sub>-Ar mixture  
 73 gas (Scaillet et al., 1992). Up to eight gold capsules were placed in a ceramic sample holder, which  
 74 was suspended between two type-S thermocouples with a Pt or Rh wire, depending on the redox  
 75 conditions. During the experiments, we maintained a thermal gradient of less than 10 °C between  
 76 the top and the bottom thermocouples. All experiments concluded with a rapid drop quench with  
 77 cooling rates of order 100°C/s (Di Carlo et al., 2006).

79 *Table 1 Composition starting material*

## 80 2.2 Capsule preparation and experimental conditions

81 The finely ground starting material was divided into three batches. Two S-bearing batches were  
82 prepared either by adding 2 wt.% native sulphur or 3 wt.% pyrrhotite (corresponding to 1.1 wt.%  
83 sulphur) and the third batch was left S-free. These bulk sulphur contents are above the sulphur  
84 solubility of basaltic melts under our experimental conditions (e.g. Moune et al. 2009; Luhr, 1990).  
85 Hence, when using the S-bearing batches directly (i.e. without mixing them with the S-free batch)  
86 as a starting material, the bulk content of sulphur should promote saturation in either sulphide or  
87 sulphate unless the coexisting fluid scavenges sulphur (see results).

88 For each experiment, six to seven Au capsules were prepared (inner and outer diameter of 2.5–2.9  
89 mm, height of 1.5 cm). Gold was used to minimize the loss of sulphur and iron. Capsules were  
90 loaded first with 3 mg of deionized water to ensure fluid saturation of the system (corresponding  
91 to about 5 wt% dissolved H<sub>2</sub>O at 200 MPa at H<sub>2</sub>O saturation, e.g. Jiménez-Mejías et al. (2021)),  
92 then with 30 mg of silicate powder prepared by mixing S- or FeS-doped powder with S-free glass  
93 in various proportions to obtain different concentrations of sulphur (Table 2). In the following, we  
94 refer to these two series as S-doped or FeS-doped charges. The weight of the capsules was measured  
95 after welding, then after a test in an oven at 125 °C for at least 1 h, and finally after the experiment  
96 to check for volatile leaks. Only charges with a difference of less than 0.0003 g were considered  
97 successful. Considering the context of La Palma 2021 eruption as summarised above, it would have  
98 been interesting to add CO<sub>2</sub> as a fluid component. This however would have needed to raise the  
99 temperature of the experiments which would have in turn prohibited the use of Au containers:  
100 Containers made of either Pt or of AuPd alloys are prone to significant alteration by sulphur, which  
101 severely complicates the interpretation of results.

102 All the experiments were run at 1040 °C and 200 MPa but with variable  $fO_2$  (between NNO-0.48  
103 and NNO+4.1), controlled by sensors of NiPd for experiments above NNO and CoPd for  
104 experiments below NNO (Taylor et al., 1992; Table 2). The  $fS_2$  of pyrrhotite-bearing charges was  
105 calculated following Froese and Gunter (1976).

106 On-going experiments aimed at determining pre-eruptive conditions of La Palma basalts (Andújar  
107 et al., submitted) suggest storage conditions of early erupted magmas at somewhat higher P and T  
108 (i.e., 300 MPa, 1060–1080°C). A number of petrological studies have shown that latter erupted  
109 magmas record higher pressures, >500 MPa, and temperatures above 1100°C (e.g., Castro and  
110 Feisel, 2022; Day et al., 2022; Ubide et al., 2023; Dayton et al., 2024). The reason of choice of our  
111 P-T conditions is essentially practical. As stressed above, the lower temperature allows us to use  
112 Au capsules, which considerably limits S loss from the melt+fluid towards the capsule (and also  
113 that of Fe loss), compared to either AuPd or Pt capsules, maintaining the physical integrity of  
114 containers. Such a low temperature is achieved by working with elevated melt water contents,  
115 which depress liquidus temperatures significantly in basaltic systems while maintaining the  
116 composition of near liquidus residual melts broadly basaltic (e.g., Sisson and Grove, 1993).  
117 Performing experiments at 300 MPa would have been possible, but the higher water content of the  
118 basaltic melts (>7 wt%) at this pressure renders those liquid poorly quenchable, even with drop

119 quench technique. Therefore, given the H<sub>2</sub>O-rich conditions of our experiments, we decided to  
120 perform the experiments at 200 MPa, with the objective of favouring the solubility of the sulphur  
121 and facilitating the quench of the glass. Nevertheless, we recognise the potential for this approach  
122 to result in differences with the natural system, in particular a higher proportion of amphibole  
123 relative to what is observed in the rocks. Higher temperatures will also affect the solubility of  
124 sulphur: for instance an increase of 50°C in the  $fO_2$  range NNO - NNO+1.5 increases the S  
125 solubility by 10-30%, if  $fS_2$  is kept constant (e.g., Boulliang and Wood, 2023).

126

### 127 **3. Analytical methods**

#### 128 *3.1 Analytical techniques*

129 Half of the recovered run products were embedded in epoxy and polished for optical inspection  
130 and, then carbon-coating, for scanning electron microscopy (SEM) using the Zeiss FEG of ISTO  
131 to identify phases, including those of quench origin.

132 Glass and minerals were analysed using a Cameca SX FIVE EMPA (CNRS-Université d'Orléans-  
133 BRGM). The analytical conditions were 15 kV, 10 nA and a peak count time of 10 s. Glasses were  
134 analysed with a defocused beam of 5, 10 or 20  $\mu$ m, depending on the size of the available glass  
135 pools. Sulphur was determined using an LPET crystal and a 20 s counting time. A focused beam  
136 was used for the minerals. Sulphides were analysed during separate sessions with the following  
137 analytical conditions: 20 kV and 50 nA, using PET and LPET crystals for S, an acquisition time of  
138 30 s, while Fe was analyzed with LIF and LLIF crystals. The Ni and Cu had acquisition times of  
139 10s. In addition, Si was used to detect possible glass contamination. At the beginning and end of  
140 the analytical session, two synthetic pyrrhotites of known compositions (as determined by X-ray  
141 analyses, (Clemente et al., 2004), Po5 and Po7, were analysed to check the stability of the  
142 calibration.

143 Three glasses with different sulphur concentrations were synthesised at 1200°C using the same  
144 experimental apparatus and starting glass. The sulphur concentrations measured by the microprobe  
145 were found to differ by less than 100 ppm relative to the added amount, validating our analytical  
146 procedure for measuring S.

147 The H<sub>2</sub>O concentration in the run products was estimated following Devine et al.(1995), analyzing  
148 at the beginning and end of each analytical session standard basaltic glasses of known water  
149 contents (F1c, F05, F3c2 and F2b, in Jiménez-Mejías et al. (2021)).

#### 150 *3.2 Mass balance and ImageJ software calculations*

151 The proportion of each phase was calculated by mass balance using a constrained least-squares  
152 model with the propagation of analytical errors of the experimental phases (Albarède, 1996; Scaillet  
153 and Evans, 1999). The proportion of glass was also calculated by processing SEM images at 100  
154  $\mu$ m magnification using ImageJ software, on a vesicle-free basis.

155 The amount of sulphur in the coexisting fluid phase was estimated by mass balance, i.e. by  
156 subtracting the masses of S in sulphur-bearing phases (glass, sulphide, sulphate) from the initial  
157 mass of sulphur, taking into account the phase percentages as calculated above. The S wt% was  
158 then calculated by determining the amount of H<sub>2</sub>O in the fluid using the same method (Table 2).

159

Run	P (MPa)	T (°C)	Time (min)	$\Delta$ NNO	log fO <sub>2</sub>	log fS <sub>2</sub> (bar)	H <sub>2</sub> O&	S% and type loaded	S wt% Glass	S wt% Fluid	Mineral assemblage

161 *Table 2 Experimental conditions, water and sulphur contents of quenched glass. H<sub>2</sub>O is calculated with the method of Devine et al*  
162 *(1996). The fS<sub>2</sub> is calculated using the method of Froese and Gunter (1976). Amph? = quench phase*

165 **4. Results**

166 The experiments generated different mineral assemblages, depending on  $fO_2$  and the amount of S  
 167 added, as shown in Fig. 1.

Fig. 1 Equilibrium phase diagram at 1040°C and 200 MPa for both S-doped (a) and FeS-doped (b) charges. Phases lie inside their stability field. Ol=olivine; Cpx= clinopyroxene; Amph = amphibole; Anhy = anhydrite; mt=magnetite.

168 In the S-doped series, anhydrite crystallizes at high  $fO_2$  while pyrrhotite is present at low  $fO_2$ . In  
 169 detail, anhydrite is found only in the charge with 2 wt.% added S at NNO+4.1, while pyrrhotite is  
 170 present with 1 wt.% and 2 wt.% S added at NNO+1.34 and NNO-0.48. Olivine occurs in almost  
 171 every charge, except for those poorer in sulphur at high  $fO_2$ . Apart from three charges with 2 wt.%  
 172 S added at NNO+2.38, 3.3 and 4.1, pyroxene is present in all experimental charges. Amphibole  
 173 distribution is more complex. It did not crystallise in charges with 2 wt.% and 1 wt.% S at  
 174 NNO+2.38, in any experiments at NNO+3.3, in the charge at 2 wt.% S under the most oxidising  
 175 conditions and in the S-free charge at NNO-0.48 (Fig.1a).

176 The phase diagram of the FeS-doped series is broadly similar. The stability range of olivine is  
 177 almost identical, except that Ol was also found in the 0.56 wt.% S charge at NNO+4.10. In the  
 178 sulphur-rich experiment at NNO+3.3, Ol was not found but owing to its low abundance in other  
 179 charges, it may have been overlooked. In the charge *lpm 1-top+S17*, olivine is present as inclusions  
 180 in the pyroxene. Pyroxene is present in all charges, except for that with 1.12 wt.% S at NNO-0.48.  
 181 FeS has a similar stability field to that identified by the S-doped series, however it is absent at 0.56  
 182 wt.% S and NNO+1.34. The amphibole field is also similar in S-doped case, except that it is not  
 183 found at NNO-0.48 (Fig.1b).

184

185

186

187

Fig. 2 Variation of oxides with SiO<sub>2</sub> of experimental glasses in S doped (coloured symbols) and FeS doped (open symbols) charges. When not shown, the error bars are smaller than the symbol size.

189 The major elements of glasses of both the S and FeS doped series (Table 3), show similar trends  
 190 (Fig. 2). SiO<sub>2</sub> increases regularly with *f*O<sub>2</sub>, from about 44 wt.% up to a of 56 wt.%, as does Al<sub>2</sub>O<sub>3</sub>,  
 191 which reaches up to 20 wt.%, reflecting the absence of plagioclase crystallisation under the  
 192 investigated conditions. Reflecting clinopyroxene crystallization, CaO shows the opposite

193 behaviour, decreasing with increasing  $\text{SiO}_2$  and  $f\text{O}_2$ . The same trend is observed for  $\text{TiO}_2$  and  $\text{FeO}$ .  
 194 The alkalis show no clear trends, with the possible exception of  $\text{Na}_2\text{O}$  which increased slightly  
 195 with  $\text{SiO}_2$ . These fractionation trends reflect the effect of the main crystallising phases, but above  
 196 all the increasing abundance of magnetite as  $f\text{O}_2$  increases (Fig. 1).

197 The concentration of sulphur in the glasses does not differ between the S- or FeS-doped  
 198 experiments (Fig.3). The charges produced at low  $f\text{O}_2$  are significantly poorer in sulphur than those  
 199 at high  $f\text{O}_2$ , the former having S concentration in the range 1000–2300 ppm, while the later have S

Fig. 3. Variation of S content of the glass with  $f\text{O}_2$  as a function of wt.% of sulphur added to the capsules. When not shown, the error bars are smaller than the symbol size.

200 contents ranging between 3300–8800 ppm. Note however that the charge doped with 0.28 wt.% S  
 201 using FeS yielded 0.8 wt.% dissolved S, which we attribute to an error in loading S to the charge.  
 202 This individual run is not further considered.

203  
 204 From inspection of the Mg# of the glass and of Fe-Mg minerals, the amount of sulphur added does  
 205 not appreciably affect their composition at fixed  $f\text{O}_2$ , though under reduced conditions

206 (<NNO+1.5), charges with higher bulk S contents tend to have phases with higher Mg# (in  
207 particular for charges with 2 wt.% added S). At high  $fO_2$  the reverse is observed. Similarly, an  
208 increase in  $fO_2$  increases slightly the Mg# of the glass and olivine, as shown in figure in  
209 Supplementary information (SIa). No clear trends with S appears for either amphibole or pyroxene  
210 compositions (SIa).

211  
212 The measured S contents in glasses saturated in pyrrhotite can be compared to those calculated  
213 using the S-solubility model of Lesne et al. (2015), which was developed for hydrous alkali-rich  
214 basalts, using the  $fS_2$  determined by pyrrhotite (Table 2). We also calculated S contents using the  
215 model of Boulliung and Wood (2023). The results are shown in Fig. 4, illustrating a general good  
216 correspondence between calculated S contents with both models and those measured, though the  
217 Boulliung and Wood (2023) model tends to underestimate S contents. Discrepancies likely reflect  
218 analytical uncertainties in pyrrhotite composition as determined by EPMA, which translates into  
219 an uncertainty in calculated  $fS_2$  of order  $\pm 1$  log unit (e.g., Whitney, 1984). For instance, increasing  
220  $\log fS_2$  of charge *lpm 29* from -1.02 to -0.5 (Table 2) would increase the calculated S content from

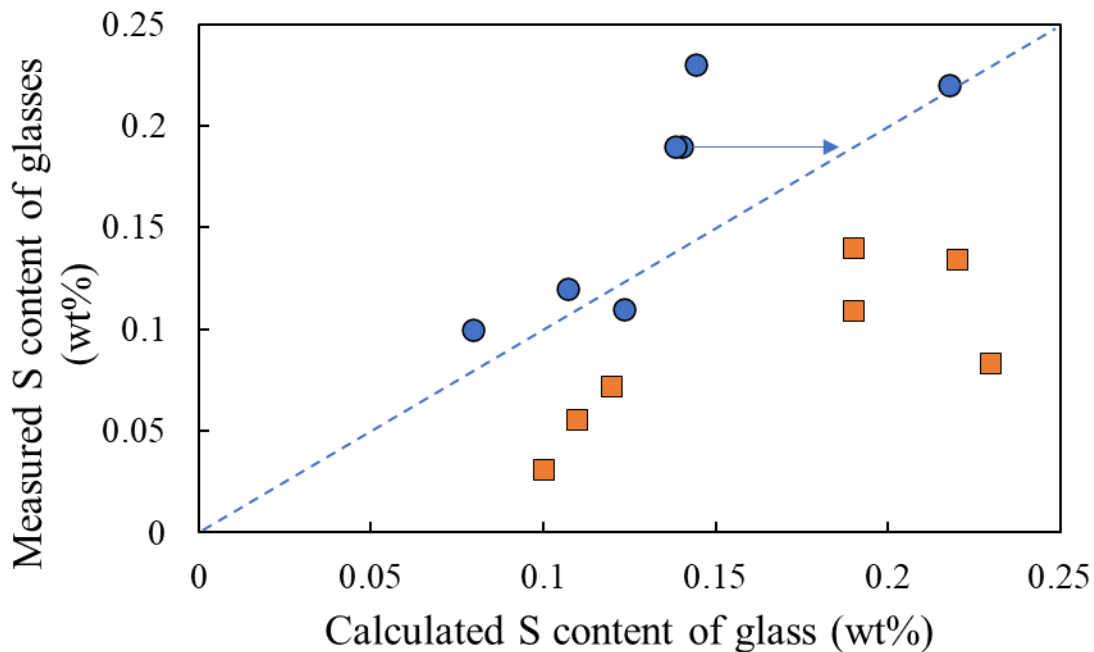

Fig. 4 Comparison between the measured S content of experimental glasses saturated in pyrrhotite with that calculated using the models of Lesne et al. (2015, blue symbols) and Boulliung and Wood (2023, orange symbols). The arrow shows the effect of increasing  $fS_2$  by 0.5 log unit on the calculated S content of melt with the model of Lesne et al. (2015).

221 0.14 wt% to 0.19 wt%, the same as the measured amount (Fig. 4).

223

Table 3 Major elements compositions, normalized to 100% anhydrous, and S contents of quenched glasses; \*Original total.

224

225 *4.2 Mass balance and ImageJ*

226 For most experiments, the volumetric percentage of glass obtained by mass balance is similar to  
227 that calculated using ImageJ (Table 4). The mass balance estimates indicate that amphibole content  
228 peaks at 40 wt.%, while clinopyroxene abundance is generally below 10 wt% and not higher than  
229 19 wt% (Table 4). Similarly, olivine proportion does not exceed 10 wt.%. The fact that amphibole  
230 proportion is higher than that in the rocks (<5 wt%, e.g. Ubide et al., 2023) reflects the lower  
231 temperature of our experiments.

232 The calculated wt.% of glass correlates well with P<sub>2</sub>O<sub>5</sub> abundance, as P is incorporated only by  
233 apatite (SIb). The dashed line in SIb is calculated assuming perfectly incompatible behaviour of  
234 P<sub>2</sub>O<sub>5</sub>. Deviations from it signify apatite formation, which occurs after 20–30 wt.% crystallisation.

238 Table 4. Phase proportions calculated by mass balance and image analyses (glass, using ImageJ software).

239 \*Amphibole partly of inferred quench origin.

241 **5. Discussion**

242 Our experiments emphasise the control of  $fO_2$  on the S-carrying capacity of silicate melts, as shown  
 243 in many previous studies (e.g., Carroll and Rutherford, 1985; Luhr, 1990; Scaillet et al., 1998; Jugo  
 244 et al., 2005). The effects of sulphur on phase relations are subtle and complex, depending on the  
 245  $fO_2$  of the experiments. In particular, amphibole is unstable at intermediate  $fO_2$ , between  $NNO+2.38$   
 246 and  $NNO+4.10$ , and S-rich conditions, while sulphide precipitates only below  $NNO+1.5$ . The  
 247 minor differences noted between the S- and FeS-doped series may be explained by the presence of  
 248 higher iron abundance in the latter case. Sulphur does not appear to affect significantly the  
 249 composition of individual phases, except for a tendency of FeMg silicate phases to become more  
 250 Mg-rich with S addition. In contrast, oxygen fugacity does affect phase compositions, in particular  
 251 olivine and glass, whose Mg# increases markedly under more oxidising conditions in both the S-  
 252 doped and FeS-doped experiments.

253 The mass balance data also show no systematic effect of sulphur on phase proportions in the  
 254 different experiments, aside from the obvious cases of sulphide or anhydrite. Here again, oxygen  
 255 fugacity appears to exert the stronger influence. As expected, the amounts of oxides, both  
 256 titanomagnetite and ilmenite, increase from reducing to oxidising conditions (Table 4). In detail,

Fig. 5 Concentration of major element versus  $SiO_2$  wt%. The experiments are compared to the water-saturated,  $1050^\circ C$  and 200-300 MPa experiments of Moune et al. (2009) and the composition A (trachyandesite) performed at  $1000^\circ C$ , 200 MPa from Luhr (1990).

257 amphibole abundance increases slightly in more oxidised runs than in reduced ones, but with no  
258 clear difference between sulphur-rich and sulphur-poor charges. This confirms that oxygen  
259 fugacity, not the amount of sulphur in the system, exerts the stronger control on phase proportions.

260 From the perspective of sulfur content in the residual glass, both sets of experiments show a  
261 consistent pattern of increasing sulfur content with elevated  $fO_2$ . The changes in melt composition  
262 resulting from  $fO_2$  variation are perhaps best illustrated by changes in Ti and Fe contents: from  
263 NNO-0.48 to NNO+4.10, both the  $TiO_2$  and FeO abundances in the glass decrease by 75 wt%,  
264 reflecting substantial crystallisation of Fe-Ti oxides. This increase in crystallisation is accompanied  
265 by an increase in abundances of  $Al_2O_3$  and  $SiO_2$  in the glass, owing to the lack of plagioclase  
266 crystallisation. These significant changes in melt composition do not, however, seem to affect the  
267 overall positive effect that  $fO_2$  has on S concentrations.

268 Our results can be compared with sulphur solubility experiments performed at comparable P-T-  
269  $H_2O$  conditions on hydrous basaltic-andesitic magmas erupted in contrasting geodynamic contexts:  
270 i) at Hekla volcano in 2000, which is taken to here represent mid-ocean ridge volcanism, though  
271 interaction with plume material is possible (Moune et al., 2009); ii) the trachyandesite magma  
272 erupted at El Chichón volcano in 1982, which belongs to an arc setting (Luhr, 1990) though some  
273 rift related processes are likely (Arce et al., 2014). The water-saturated, 1050°C and 200–300 MPa  
274 experiments of Moune et al., (2009), and the composition A (trachyandesite) performed at 1000°C,  
275 200 MPa from Luhr (1990), are compared with our data in Fig. 5. At any given  $SiO_2$ , differences  
276 in some oxide contents (e.g., CaO,  $Al_2O_3$ ) are evident. These can be attributed to bulk  
277 compositional effects (Fig. 5) and to slightly different experimental conditions which impart  
278 different degrees of crystallization. The broad correspondences remain when oxygen fugacity is  
279 considered (Figure S1c). The  $TiO_2$  content of the andesitic charges of Moune et al (2009) and Luhr  
280 (1990) are lower than ours, reflecting the lower Ti content of the corresponding starting materials.  
281 This is particularly evident in the Luhr (1990) experiments, in which the concentration of  $TiO_2$  in  
282 the starting composition is so low that no difference exists between reduced and oxidised  
283 conditions. Based on these data, it appears that the presence of sulphur does not significantly affect  
284 the concentrations of the major elements of residual melts. Irrespective of geodynamic context, the  
285 factor that most influences melt composition is oxygen fugacity.

286 As in many previous studies(e.g., Carroll and Rutherford, 1985; Liu et al., 2007; Moune et al.,  
287 2009), our experiments reveal a significant difference in the amount of sulphur in the glasses  
288 between low and high  $fO_2$  experiments (Fig. 6). At low  $fO_2$ , the sulphur concentrations in the  
289 glasses measured by Moune et al (2009) and Luhr (1990) are comparable to those found in our  
290 experiments, most falling in the interval 1000–2500 ppm. Furthermore, as noted by Moune et al.  
291 (2009), at  $fO_2$  between NNO-0.48 and NNO1.34, sulphur abundance in the glass increases in  
292 proportion to the increase of added sulphur, until bulk S exceeds 0.5 wt.% (Fig 6). Thereafter, the  
293 S content in the glass levels off at  $2000 \pm 100$  ppm. At  $fO_2$  above NNO+2.38, a similar pattern is  
294 observed with a positive trend up to about 1 wt.% sulphur added, at which point the dissolved S  
295 levels off at 0.7 wt%.

Fig.6 Sulphur concentration in the melt versus the amount of sulphur added in the runs. The experiments are compared to the water-saturated, 1050°C and 200-300 MPa experiments of Moune et al. (2009) and the composition A (trachyandesite) performed at 1000°C, 200 MPa from Luhr (1990). The dashed trendlines are calculated assuming an incompatible behaviour of S at 50%, 25% and 0% of crystallization.

296 The experiments of Luhr (1990) carried out under oxidised conditions resulted in lower S  
 297 concentrations in the glass than we obtained for the same amount of sulphur added. Anhydrite  
 298 crystallization in the Luhr (1990) runs, which did not occur in our experiments under the same  
 299 conditions, likely explains this. The levelling off of both trends at high bulk S contents likely results  
 300 from the buffering effect of other S-bearing phases. In addition to fluid, under reducing conditions  
 301 this would be sulphide, while under oxidising conditions this would be anhydrite. Oxidised charges  
 302 with less than 0.5 wt.% added S fall on, or close to, the 1-to-1 correlation line, which shows that  
 303 under these conditions a significant proportion of S resides in the melt phase (those data that fall  
 304 above the 1/1 line reflect the amount of crystallisation of charges).

305

306

307

308 5.1 Significance for understanding the La Palma 2021 eruption

309 The pre-eruptive  $fO_2$  of Cumbre Vieja 2021 basanite has been broadly constrained from V  
 310 systematics in olivine to fall between NNO+0.6 and NNO+1.3 (Day et al., 2022). We note however  
 311 that a recent reassessment of V behaviour has concluded that current formulations of this  
 312 oxybarometer tend to overestimate  $fO_2$  by up to 0.7 log unit in hydrous basalts (Erdmann et al.,  
 313 2024), which would bring the La Palma magma redox state into the NNO-NNO+1 range.

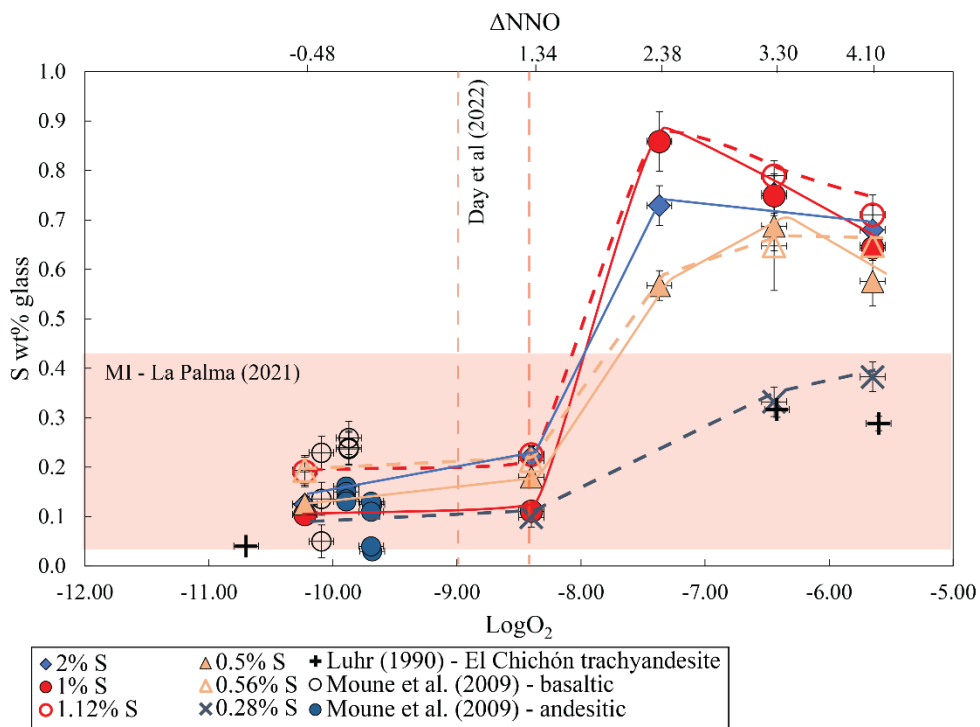

Fig. 7 Sulphur concentration in the melt versus  $\log fO_2$ . The experiments are compared to the water-saturated, 1050°C and 200-300 MPa experiments of Moune et al., 2009 and the composition A (Trachyandesite) performed at 1000°C, 200 MPa from Luhr, 1990; MI-La Palma (2021) = S wt% in melt inclusions (Castro and Feisel, 2022; Burton et al., 2023; Dayton et al., 2024).

314 Considering a NNO-NNO+1.3 range, our data indicate that under these conditions the bulk magma  
 315 S content was ~2500–5000 ppm, a significant part of which was dissolved in the melt, broadly  
 316 consistent with melt inclusion analyses (Fig.7) (e.g., Castro and Feisel, 2022; Burton et al., 2023;  
 317 Dayton et al., 2024). Note that the highest S content so far measured in melt inclusions (4800 ppm,  
 318 Burton et al., 2023) points to  $fO_2$  at the upper end of the range inferred from V in olivine (Fig. 10),  
 319 or higher temperatures. The occasional occurrence of sulphides (as inclusions in phenocrysts) in  
 320 erupted products (Andujar et al., submitted) is consistent with our experiments at NNO+1.34,  
 321 although the absence of sulphide in the matrix glass suggests that the erupting magma was not  
 322 saturated in sulphide.

323 Our experiments show that to achieve the observed S content analysed in melt inclusions of La  
 324 Palma 2021 basanite (around 3000 ppm S) at the inferred pre-eruptive  $fO_2$  between NNO+0.6 and  
 325 NNO+1.6 (Day et al., 2022), the  $fS_2$  should be around 0.1–1 MPa, as recorded by the composition  
 326 of pyrrhotite in our run products (Table 2).

327 Using these constraints, in what follows we have have carried out calculations aimed at modelling  
328 the fluid phase composition for three different scenarios: (1) we have first calculated the fluid  
329 composition at equilibrium with the basanite magma lying in the crustal reservoir, which is inferred  
330 to lie at ~ 300 MPa, based on seismic source locations and petrological arguments (e.g., D’Auria  
331 et al., 2022; Del Fresno et al., 2023b; Ubide et al., 2023; Dayton et al., 2024; Andujar et al.,  
332 submitted). (2) We next perform calculations of magma degassing during uprise, starting at 300  
333 MPa with variable amount of exsolved fluid. (3) Finally, we simulate degassing from higher  
334 pressures (i.e. deeper levels) and higher temperature (about 1125°C), in keeping with the elevated  
335 CO<sub>2</sub> dissolved contents (up to 1.2 wt%) retrieved from olivine inclusions (e.g., Zanon et al., 2023;  
336 Dayton et al., 2024) and seismic data (e.g., D’Auria et al., 2022; Del Fresno et al., 2023) which  
337 point to a mantle source at 400-800 MPa.

338 (1) For the first step, we use the following constraints: a pre-eruptive dissolved CO<sub>2</sub> content  
339 ranging from 3000–5000 ppm, and a dissolved H<sub>2</sub>O<sub>melt</sub> of 1–3 wt%, drawing on melt  
340 inclusion analyses (e.g., Burton et al., 2023; Dayton et al., 2023). We perform calculations  
341 at 1080°C, which corresponds to the inferred temperature for the basaltic magma at  
342 equilibrium with amphibole ((González-García et al., 2023)González-García et al., 2023;  
343 Sandoval-Velasquez et al., 2023; Andujar et al., submitted), using an MRK equation of state  
344 for fluid coupled to the S solubility model of Lesne et al. (2015), calibrated for alkali-rich

Fig. 8 (a) Evolution of the S content of the excess fluid in the reservoir at 300 MPa with  $fO_2$ . (b) Evolution of the ratio  $X\text{CO}_2/X\text{SO}_2$  of the fluid with  $\Delta\text{NNO}$ . The calculations have been made at three different  $fS_2$ ; The thick green line shows the  $X\text{CO}_2/X\text{SO}_2$  ratio of volcanic gases measured at la Palma during explosive emissions (Burton et al., 2023). See text for details.

345 basalt melts, and to the CO<sub>2</sub>-H<sub>2</sub>O solubility model of Jímenez-Mejías et al. (2021),  
 346 calibrated for a basanite from the Canary islands. The calculation then yields the saturation  
 347 pressure in H<sub>2</sub>O, CO<sub>2</sub>, SO<sub>2</sub> and H<sub>2</sub>S fluid species. The key assumption is that of equilibrium  
 348 between the fugacities of volatiles in the fluid with those in the melt (e.g., Lesne et al.,  
 349 2015). Given uncertainty in the magma redox state, and in its possible variation during  
 350 decompression (e.g., Burgisser and Scaillet, 2007; Moussallam et al., 2016), we performed  
 351 the calculations for a range of  $fO_2$  between NNO-2 and NNO+2. Fig 8a shows the variation  
 352 of S content of the fluid in the reservoir at 300 MPa with  $fO_2$ , calculated for three different  
 353  $fS_2$ . This calculation gives the composition of fluids at the surface if they could leave the  
 354 crustal reservoir on their own, i.e. without being accompanied by melts, and traversing the  
 355 crustal section unmodified. Although this scenario is possibly not directly applicable to the  
 356 La Palma 2021 eruption, it provides context for the interpretation of gas monitoring during  
 357 repose periods. In the range of  $fO_2$  inferred by Day et al. (2022), the S content of the fluid  
 358 falls between 1 and 10 wt%, depending on  $fS_2$ , comparable with S contents calculated for  
 359 more silicic compositions (e.g., Scaillet et al., 2003) and to that calculated by mass balance

360 for most of our experiments (Table 2). The calculations further show that  $X_{CO_2}/X_{SO_2}$   
 361 progressively decreases as  $f_{O_2}$  increases (Fig. 8b). In the  $f_{O_2}$  interval NNO+0.7 to  
 362 NNO+1.3,  $X_{CO_2}/X_{SO_2}$  ranges from  $\sim 2$  up to  $\sim 100$ , within the range of measurements of  
 363 volcanic gas emissions during the 2021 La Palma eruption (Burton et al., 2023). Measured  
 364 ratios range from to 35 for explosive activity down to less than 10 for effusive emissions  
 365 (Burton et al., 2023), and the higher end is to be favoured as a characteristic of gas-rich  
 366 magma, presumably of deeper provenance.

367 (2) We next consider degassing during magma ascent, especially of S and H<sub>2</sub>O, which can  
 368 exsolve and separate from the melt extensively near the surface (Oppenheimer et al., 2014).  
 369 The full calculation should also take into account the possible role of an excess fluid in the  
 370 crustal reservoir. For instance, the bulk CO<sub>2</sub> content of La Palma magma has been estimated  
 371 to be at  $4 \pm 1.5$  wt% based on the measured S emissions and the average  $X_{CO_2}/X_{SO_2}$  ratio  
 372 (Burton et al., 2023). Taking a conservative value of 3 wt% fluid (with 3 wt% H<sub>2</sub>O and

Fig. 9 (a) Evolution of total amount of  $SO_2$  degassed by  $0.2 \text{ km}^3$  of basanite magma with  $f_{O_2}$  expressed as  $\Delta NNO$ . (b) Evolution of the  $X_{CO_2}/X_{SO_2}$  ratio of the gas emitted at the vent with  $\Delta NNO$ . The calculations have been performed at  $1080^\circ\text{C}$ .

373 3000 ppm CO<sub>2</sub> dissolved in melt, which correspond to the volatile contents of a fluid  
 374 saturated basanite at 300 MPa), we calculate as a function of oxygen fugacity both the total

375 amount of S released by the 0.2 km<sup>3</sup> of erupted magma, and the XCO<sub>2</sub>/XSO<sub>2</sub> ratio of the  
376 gas at the vent (i.e. melt+fluid), accounting for the 400– 600 ppm of S that remains in matrix  
377 glass (Fig. 12). With these constraints and assuming an *f*O<sub>2</sub> of ~ NNO+1, 2-4 Mt SO<sub>2</sub>, we  
378 find that the pre-eruptive magma must have had an *f*S<sub>2</sub> in the range 0.1-1 MPa (Fig. 9a). A  
379 *f*S<sub>2</sub> significantly lower than 0.1 MPa will fall short in reproducing this figure. With respect  
380 to the final XCO<sub>2</sub>/XSO<sub>2</sub> ratio (i.e. the one measured at the vent), the same set of calculations  
381 shows that such a ratio displays a bell-shaped pattern, with a maximum in between NNO  
382 and NNO+0.5 (fig.9b). For *f*S<sub>2</sub> values in the range 0.1-1 MPa, the maximum possible  
383 XCO<sub>2</sub>/XSO<sub>2</sub> ratio is about 30, lying slightly above NNO, i.e. at an *f*O<sub>2</sub> more reduced than  
384 that retrieved from V systematic.

385 It is also interesting to consider the  $X_{H_2O}/X_{SO_2}$  ratio, which was also measured during La Palma  
 386 2021 eruption (Burton et al., 2023). The variation of this ratio with  $fO_2$  (as for  $X_{CO_2}/X_{SO_2}$ ) with  
 387 the amount of excess fluid in the reservoir is shown in Fig. 10b. Here the calculations are made for  
 388 a magma at 300 MPa with 4000 ppm  $CO_2$ , 2 wt%  $H_2O$  and for  $fS_2=0.2$  MPa, at  $1080^\circ C$ , also  
 389 consistent with available melt inclusion and phase equilibrium constraints for the top portion of the  
 390 plumbing system (González-García et al., 2023; Sandoval-Velasquez et al., 2023; Andujar et al.,  
 391 submitted). As with the previous calculations, both ratios exhibit a similar bell shaped trend with  
 392  $fO_2$ . They are both sensitive to the amount of free fluid: as it increases, so the  $X_{H_2O}/X_{SO_2}$  ratio  
 393 drops, while the  $X_{CO_2}/X_{SO_2}$  increases, due to the contrasting  $H_2O$  and  $CO_2$  contents in melt and  
 394 fluid phases. Gas emissions during the most explosive phase of La Palma eruption had an

Fig. 10. Evolution of the  $X_{H_2O}/X_{SO_2}$  (a) and  $X_{CO_2}/X_{SO_2}$  (b) ratios of gases vented at 0.1 MPa with  $fO_2$ , for different amounts of exsolved fluid in the reservoir at 300 MPa. (c) Evolution of the mass of  $SO_2$  produced for the three different amounts of fluid. In all panels the thick horizontal green dashed line indicates the measured value of the corresponding parameter.

395  $X_{CO_2}/X_{SO_2}$  of  $\sim 35$  and an  $X_{H_2O}/X_{SO_2}$  ratio of  $\sim 22$  (Burton et al., 2023). For the conditions  
 396 shown in Fig. 10, these ratios are reproduced at around  $NNO+0.5$  to  $NNO+1$  for 6 wt% excess  
 397 fluid, broadly consistent with previous inferences. Clearly, the amount of  $SO_2$  released increases  
 398 with the amount of pre-eruptive fluid in the crustal reservoir (Fig. 13c). For this set of conditions,  
 399  $fO_2$  in the range  $NNO+1$  to  $NNO+1.5$  are required to yield 4 Tg  $SO_2$ . These calculations point  
 400 therefore to the presence of a significant amount of free fluid in the plumbing system, as indicated  
 401 by previous work (e.g., Burton et al., 2023; Sandoval-Velasquez et al., 2023; Zanon et al., 2024)).

402 (3) The last set of calculations explores the deeper part of the plumbing system. As noted  
 403 earlier, melt inclusions hosted by olivine record a range of dissolved  $CO_2$ , up to 5000 ppm  
 404 (e.g., Dayton et al., 2024). If account is made for the occurrence of exsolved fluid in the

Fig. 11(a) Evolution of total amount of  $SO_2$  degassed by  $0.2 \text{ km}^3$  of basaltic magma with  $fO_2$  expressed as  $\Delta NNO$  with increasing  $CO_2$  from 5000 ppm to 10000 ppm. (b) Evolution of the  $X_{CO_2}/X_{SO_2}$  ratio of the gas emitted at the vent with  $\Delta NNO$  with increasing  $CO_2$  from 5000 ppm to 10000 ppm. The calculations have been performed at  $1125^\circ\text{C}$ . In all panels the measured values of the corresponding parameter are in green dashed line (burton et al., 2023).

405 melt inclusions, the CO<sub>2</sub> content rises up to 1.2 wt% (Dayton et al., 2024), underscoring the  
406 deep mantle provenance of some of the magma erupted during the eruption. We have  
407 therefore also carried out calculations using higher dissolved CO<sub>2</sub>, from 5000 to 10000 ppm  
408 (corresponding to pressures in the range 400-800 MPa). We keep the excess fluid at 3 wt%  
409 as in most calculations above and the amount of H<sub>2</sub>O dissolved at 3 wt% (hence the total  
410 amount of volatiles sums up to over 6 wt%). Results are shown on figure 11. In terms of  
411 XCO<sub>2</sub>/XSO<sub>2</sub>, increasing pressure makes high  $fS_2$  (1 MPa) less likely than a moderate one  
412 (0.1 MPa), since the family of curves corresponding to  $fS_2=1\text{MPa}$  does not allow to  
413 reproduce the observed XCO<sub>2</sub>/XSO<sub>2</sub> ratio of vented gases. Note that for an  $fS_2=0.1\text{MPa}$ ,  
414 the intersection happens at around NNO+1, which is an  $fO_2$  slightly lower than the one  
415 inferred by Day et al. (2022).

416

417 For what regards the amount of SO<sub>2</sub> released, a magma with an  $fS_2$  of 1 MPa would require an  
418  $fO_2$  slightly over NNO, while that with an  $fS_2$  of 0.1 MPa would require slightly more oxidizing  
419 conditions, both  $fS_2$  being compatible with the inferred range of redox state of La Palma magma  
420 (Day et al., 2022).

421 The above sets of calculations show that reproducing the observations reported for La Palma  
422 eruption, in particular the S content of melt inclusions, the gas composition, and the amount of S  
423 released, requires a subtle combination of  $fO_2$ ,  $fS_2$  and amount of fluid of the magma (in addition  
424 to T and P). Elevated S contents in the melt point to  $fO_2$  conditions above NNO (Fig.6). The  $fS_2$   
425 should be in the vicinity of 0.1 MPa in order to reproduce the amount of SO<sub>2</sub> released (Fig 8a, 10c).  
426 An  $fS_2$  too high will not be compatible with the observed XCO<sub>2</sub>/XSO<sub>2</sub> ratio, in particular if the  
427 majority of outgassed sulphur is sourced from magma of deep mantle provenance (Fig 11). The  
428 amount of fluid in the reservoir is also critical if the final fluid released is to have an XH<sub>2</sub>O/XSO<sub>2</sub>  
429 lower than XCO<sub>2</sub>/XSO<sub>2</sub>, as observed. According to our calculations, amounts of fluid significantly  
430 below 5 wt% (at 300 MPa) cannot satisfy this constraint (Fig. 10). An XH<sub>2</sub>O/XSO<sub>2</sub> ratio of 22 and  
431 an XCO<sub>2</sub>/XSO<sub>2</sub> ratio of 35 requires  $fO_2$  to be ~ NNO+0.6, which is lower than inferred, and which  
432 would not sustain elevated S content in the melt (Fig. 6). This illustrates the challenge of delineating  
433 conditions that satisfy all observations. Beyond model uncertainties, such discrepancies may also  
434 reflect fractionation of gases during magma ascent, either near the surface (Burton et al., 2023), or  
435 deeper in the plumbing system. Uncertainties in magma's  $fO_2$  remain large also and more work is  
436 needed to refine La Palma redox state, given the importance of this parameter on S behaviour. An  
437 additional caveat is that observed gases at La Palma likely represent the mixture of volatiles sourced  
438 from magma already stagnating in the reservoir, possibly years before the eruption (e.g., Day et al.,  
439 2022; Andujar et al., submitted), as well as mantle-derived volatile-rich magmas (Zanon et al.,  
440 2024; Dayton et al., 2024), injected shortly before or during eruption. Such processes, likely in  
441 play, are not captured by our treatment.

442

443 **6. Conclusions**

444 We have shown that the composition of the residual glass as well as the phase relationships and  
445 their proportions are primarily influenced by oxygen fugacity, but also by the amount of sulphur in  
446 the system, though to a lesser extent. Similarly, our experiments emphasise the considerable  
447 influence of  $fO_2$  on the solubility of S in silicate melts (Figs. 5,6). Between NNO-0.48 and  
448 NNO1.34, the maximum S concentration in the residual glass is  $0.2\pm 0.01$  wt%, while at oxygen  
449 fugacity above NNO+2.38, the maximum value is 0.7–0.8 wt%. These limits are imposed by the  
450 buffering effect of sulphide/sulphate phases in addition to the fluid.

451 Modelling of the fluid phase composition using an MRK equation of state for fluid and the models  
452 of Lesne et al. (2015) and Jiménez-Mejías et al. (2021) for volatile solubilities, shows that the S  
453 content of the fluid lies between 1 and 10 wt%, depending on  $fS_2$ . Overall, the calculations show  
454 that in order to expel 2-4 Mt of  $SO_2$ , the pre-eruptive magma must have had a  $fS_2$  at the 0.1 MPa  
455 level (Fig. 11a) with an  $fO_2$  above NNO, in general agreement with the oxidised character inferred  
456 for hot spot basalts (Moussallam et al., 2019), and coexisted with a significant amount of exsolved  
457 fluid in the crustal reservoir.
